We analyzed GWAS SNP data that passed quality control for 12,496 cases (6,191 classified as GBM and 5,819 classified as non-GBM tumors) and 18,190 controls from eight studies with individuals of European ancestry, a new GWAS of 4,572 cases and 3,286 controls performed by the Glioma International Case Control Consortium (GICC) (Supplementary Table 1), a new GWAS of 1,591 cases and 804 controls from the University of California, San Francisco (UCSF)-Mayo, and six previously reported GWAS[9, 10, 13] totaling 6,405 cases and 14,100 controls (Supplementary Table 2). To increase genomic resolution, we imputed >10 million SNPs. Quantile–quantile (Q-Q) plots for SNPs with a minor allele frequency (MAF) >1% after imputation did not show evidence of substantive overdispersion (λ = 1.02–1.10, λ_{90} = 1.02–1.05; Supplementary Fig. 1). We derived joint ORs and 95% confidence intervals (CIs) under a fixed-effects model for each SNP with MAF >1% and associated per-allele principal component (PCA) corrected P-values for all glioma, GBM and non-GBM cases versus those for the controls (Fig. 1).

In the combined meta-analysis, among previously published glioma risk SNPs, those for all glioma at 17p13.1 (*TP53*), for GBM at 5p15.33 (*TERT*), 7p11.2 (*EGFR*), 9p21.3 (*CDKN2B–AS1*) and 20q13.33 (*RTEL1*), and for non-GBM tumors at 8q24.21 (*CCDC26*), 11q23.2, 11q23.3 (*PHLDB1*) and 15q24.2 (*ETFA*) showed even greater evidence for association (Supplementary Fig. 2 and Supplementary Table 3). SNPs at 10q25.2 and 12q12.1 for non-GBM tumors retained genome-wide significance (i.e., $P < 5.0 \times 10^{-8}$). Associations at the previously reported 3q26.2 (near *TERC*)[11] and 12q23.33 (*POLR3B*)[10] loci for GBM did not retain statistical significance (P values for the most associated SNPs are 2.68×10^{-5} and 1.60×10^{-5}, respectively; Supplementary Table 3).

In addition to previously reported loci, we identified genome-wide significant associations marking new risk loci (Table 1, Supplementary Fig. 3 and Supplementary Data 1) for GBM

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

at 1p31.3 (rs12752552; $P = 2.04 \times 10^{-9}$), 11q14.1 (rs11233250; $P = 9.95 \times 10^{-10}$), 16p13.3 (rs2562152; $P = 1.93 \times 10^{-8}$), 16q12.1 (rs10852606; $P = 1.29 \times 10^{-11}$) and 22q13.1 (rs2235573; $P = 1.76 \times 10^{-10}$) and for non-GBM tumors at 1q32.1 (rs4252707; $P = 3.34 \times 10^{-9}$), 1q44 (rs12076373; $P = 2.63 \times 10^{-10}$), 2q33.3 (rs7572263; $P = 2.18 \times 10^{-10}$), 3p14.1 (rs11706832; $P = 7.66 \times 10^{-9}$), 10q24.33 (rs11598018; $P = 3.39 \times 10^{-8}$), 11q21 (rs7107785; $P = 3.87 \times 10^{-10}$), 14q12 (rs10131032; $P = 5.07 \times 10^{-11}$) and 16p13.3 (rs3751667; $P = 2.61 \times 10^{-9}$). Conditional analysis confirmed the existence of two independent association signals at 7p11.2 (*EGFR*) as previously reported[7] but did not provide evidence for additional signals at any of the other established identified risk loci or at the 13 newly identified loci. Case-only analyses con-firmed the specificity of 11q14.1, 16p13.3 and 22q13.1 associations for GBM and of 1q44, 2q33.3, 3p14.1, 11q21 and 14q12 associations for non-GBM tumors (Fig. 2 and Supplementary Table 4). Collectively, our findings provide strong evidence for specific associations for the different glioma subtypes, consistent with their previously described distinctive molecular profiles, presumably resulting from different etiological pathways.

Across the new and known risk loci, we found a significant enrichment of overlap with enhancers in H9-Derived neuronal progenitor cells ($P = 8.2 \times 10^{-5}$; Supplementary Data 2). These observations support the assertion that the loci identified in the GWAS influence glioma risk through effects on neural *cis* regulatory networks and that they are strongly involved in transcriptional initiation and enhancement. To gain further insight into the biological basis for associations at the 13 new risk loci, we performed an expression quantitative trait loci (eQTL) analysis using RNA-seq data on ten regions of normal human brain from up to 103 individuals from the Genotype–Tissue Expression (GTEx) project[16] and blood eQTL data on 5,311 individuals from Westra *et al.*[17]. We used summary-level mendelian randomization (SMR)[18] analysis to test for a concordance between signals from GWAS and *cis* eQTL for genes within 1 Mb of the sentinel and correlated SNPs ($r^2 > 0.8$) at each locus (Supplementary Data 3) and derived b_{XY} statistics, which estimate the effect of gene expression on glioma risk. Additionally, for each of the risk SNPs at the 13 new loci (as well as the correlated variants), we examined published data[19, 20] and made use of the online resources HaploRegv4, RegulomeDB and SeattleSeq for evidence of functional effects (Supplementary Table 5).

At 16q12.1, the GBM association signal was significantly associated with *HEATR3* expression in nine of ten regions of the brain (PSMR = 3.38×10^{-6} to 6.55×10^{-10}; $b_{XY} = 0.14$–0.24; Supplementary Fig. 4 and Supplementary Data 3). The risk allele ‘C’ of rs10852606 that was associated with reduced *HEATR3* expression was consistent with differential expression of *HEATR3* being the functional basis of the 16q12.1 association. The observation that variation at 16q12.1 is associated with risk of testicular[21] (rs8046148; pairwise r^2 and D' with rs10852606 of 0.67 and 1.0, respectively) and esophageal[22] (rs4785204; pairwise r^2 and D' with rs10852606 of 0.16 and 1.0, respectively) cancer suggests that the locus has pleiotropic effects on tumor risk, which are compatible with generic effects as shown by the observation of a *HEATR3* eQTL signal in blood (*PSMR* = 5.84×10^{-11}; $b_{XY} = 0.30$).

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Similarly, significant associations between gene expression and glioma risk were observed at the GBM loci 1p31.3 (*JAK1*, brain cortex and cerebellar hemisphere), 16p13.3 (*POLR3K*, whole blood) and 22q13.1 (*CTA-228A9.3*, brain cerebellum; *PICK1*, brain hippocampus) (Supplementary Fig. 4 and Supplementary Data 3). The non-GBM association at 1q32.1 marked by rs4252707 (Supplementary Fig. 3) maps to intron 8 of the gene encoding MDM4, a p53-binding protein. The SNP rs4252707 is in strong linkage disequilibrium (LD) with rs12031912 and rs12028476 ($r^2 = 0.92$), both of which map to the *MDM4* promoter. Although no significant eQTL was shown in any brain tissue, an association with *MDM4* was seen in blood (PSMR = 4.74 × 10^{-6}; $b_{XY} = 0.31$; Supplementary Fig. 4 and Supplementary Data 3). Overexpression of *MDM4* is a feature in glioma tumors containing wild-type *TP53* and no amplification of the *MDM2* gene, consistent with *MDM4* amplification being a mechanism by which the p53-dependent growth control is inactivated[23].

The 1q44 association with non-GBM that is marked by rs12076373 maps to intron 8 of *AKT3*, whose encoded product is one of the major downstream effectors of phosphatidylinositol 3-kinase (PI3K) and is highly expressed during active neurogenesis, with haploinsufficiency causing postnatal microcephaly and agenesis of the corpus callosum[24]. Notably, *AKT3* is hyper-expressed in glioma, thus having a role in tumor viability by activating DNA repair[25]. Although rs12076373 does not map to a regulatory element, the correlated SNPs rs12124113 ($r^2 = 0.94$) and rs59953491 ($r^2 = 0.90$) locate within an enhancer element in brain cells and tissues, including H9-derived neuronal progenitor cultured cells, cortex-derived primary cultured neurospheres and NH-A astrocytes.

The 3p14.1 association with non-GBM that is marked by rs11706832 localizes to intron 2 of *LRIG1*. Although we did not identify an eQTL in this gene, *LRIG1* is highly expressed in the brain and is a pan-negative regulator of the epidermal growth factor receptor (EGFR) signaling pathway, which inhibits hypoxia-induced vasculogenic mimicry via EGFR–PI3K–AKT pathway suppression and epithelial-to-mesenchymal transition[26]. Reduced *LRIG1* expression is linked to tumor aggressiveness, temozolomide resistance and radio-resistance[27, 28]. We have previously shown an association for glioma at *EGFR* (7p11.2)[7], which is well established to be pivotal in both the initiation of primary GBM and the progression of lower-grade glioma to grade IV. Although speculative, our new findings now suggest a more extensive pathway involving variation at *LRIG1* and *AKT3*.

Of particular interest is rs7572263, which maps to 2q33.3, localizes within intron 3 of *C2orf80* and is 50 kb telomeric to *IDH1*. Mutation of *IDH1* is a driver for gliomagenesis[29, 30] and is responsible for the CpG island methylator (G-CIMP) phenotype[31, 32]. Mutations in *IDH1* predominate in non-GBM glioma[33, 34]; therefore, the association at 2q33.3 is plausible as a basis for susceptibility to non-GBM glioma. In the absence of convincing eQTL or other functional support, this does not preclude *C2orf80* or another gene mapping to the region of LD as being the functional basis for the 2q33.3 association.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

The maintenance of telomeres is central to cell immortalization, and it has a central role in gliomagenesis[35]. We have previously shown that the risk of GBM is strongly linked to genetic variation in the telomere-related genes *TERT* (5p15.33) and *RTEL1* (20q13.33), and possibly also *TERC* (3q26.2)[8, 9, 11]. The 10q24.33 association with non-GBM that is marked by rs11598018 lies intronic to *OBFC1*, which functions in a telomere-associated complex that protects telomeres independently of POT1 (ref. 36). The CST complex, whose components are encoded by *OBFC1, CTC1*, and *TEN1*, competes with shelterin for telomeric-DNA-inhibiting telomerase-based telomere extension[37]. The significant association between the risk of non-GBM tumors and *OBFC1* variation is particularly of note in light of our recent exome-sequencing report demonstrating that rare germline loss-of-function mutations in genes that encode components of the shelterin complex are a cause of familial oligodendroglioma[38]. The glioma risk alleles at *TERT, TERC* and *OBFC1* are associated with increased leukocyte telomere length, thereby supporting a relationship between genotype and biology (Supplementary Table 6)[35, 39, 40]. However, the *RTEL1* locus is not consistent with such a postulate, and recent data that have not shown a relationship between mutations in the *TERT* promoter and telomere length in glioma[41] raise the possibility of a role for extratelomeric effects.

The deregulation of pathways involved in telomere length and EGFR signaling are thus consistent with glioma risk being governed by pathways that are important in the longevity of glial cells, and they substantiate early observations that genetic susceptibility to GBM and non-GBM tumors is highly distinct, presumably reflecting different etiologies between GBM and non-GBM tumors (Fig. 2).

The other associations we identified mark genes with varying degrees of plausibility for having a role in glioma oncogenesis. The GBM association at 16p13.33 marked by rs2562152 localizes 3 kb telomeric to *MPG*, which encodes a *N*-methylpurine DNA glycosylase whose expression is linked to temozolomide resistance in glioma[42]. Although attractive as a candidate, the only genes for which there was found to be a significant association between expression and glioma risk were *POLR3K* and *C16ORF33* in blood (Supplementary Fig. 4 and Supplementary Data 3). At 1p31.3, only *JAK1* provided convincing evidence for a significant eQTL with glioma risk SNPs in brain tissue. The strongest association was shown in the cortex ($P_{SMR} = 1.61 \times 10^{-6}$; $b_{XY} = 0.22$; Supplementary Fig. 4 and Supplementary Data 3), with the risk allele 'T' of rs12752552 showing increased *JAK1* expression. The *cis*-eQTL signal for *JAK1* in the cortex maps from 65.3 Mb to 65.35 Mb and shows a consistent direction of effect with the glioma-associated SNPs. JAK1–STAT6 signaling is increasingly being recognized to be relevant in glioma progression[43]. Hence, although *JAK1* remains an attractive candidate mechanistic basis for the glioma association at 1p31.3, we cannot exclude the possibility that the cluster of SNPs between 65.3 Mb and 65.35 Mb contains the true causal variant. In the absence of functional data, potential target genes for associations at 11q14.1 (GBM), 16p13.3 (non-GBM), 11q21 (non-GBM) and 14q12 (non-GBM) remain to be elucidated.

In conclusion, we have performed the largest glioma GWAS to date and have identified 13 new glioma risk loci, thereby providing further evidence for a polygenic basis of genetic susceptibility to glioma. Histological classification of glioma is, in part, being superseded by

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

molecular profiling[34, 44]; hence, it is important to understand the biology behind these risk variants in the context of molecularly defined glioma subtypes. Currently identified risk SNPs for glioma account for, at best, ~27% and ~37% of the familial risk of GBM and non-GBM tumors, respectively (Supplementary Table 7). Therefore, further GWAS-based analyses in concert with functional analyses should lead to additional insights into the biology and etiological basis of the different glioma histologies. Notably, such information can inform gene discovery initiatives and thus have a measurable effect on the successful development of new therapeutic agents.

ONLINE METHODS

Ethics

Collection of patient samples and associated clinico-pathological information was undertaken with written informed consent and relevant ethical review board approval at the respective study centers in accordance with the tenets of the Declaration of Helsinki. Specifically informed consent and ethical board approval was obtained from the South-East Multicentre Research Ethics Committee (MREC) (UK), the Scottish MREC (UK), the APHP ethical committee-CPP (Comité de Protection des Personnes) (France), the Ethics Commission of the Medical Faculty of the University of Bonn (Germany), the University of Texas MD Anderson Cancer Institutional Review Board (USA), the Mayo Clinic Office for Human Research Protection (USA), the UCSF Committee on Human Research (USA), the University Hospitals of Cleveland Institutional Review Board (USA) and the Cleveland Clinic Institutional Review Board (board for the Case Comprehensive Cancer Center) (USA). The diagnosis of glioma (ICDO-3 codes 9380-9480 or equivalent) was established through histology in all cases in accordance with World Health Organization guidelines. Every effort was made to classify tumors as GBM or non-GBM.

GWAS data sets

GICC, UK, French, German, MDA, SFAGS and GliomaScan—Studies participating in GICC are described in Amirian *et al.*[46] and in Supplementary Table 1. Briefly, they comprise 5,189 glioma cases and 3,827 controls that were ascertained through centers in the USA, Denmark, Sweden and the UK. Cases had newly diagnosed glioma, and controls had no personal history of central nervous system tumor at the time of ascertainment. Detailed information regarding recruitment protocol is given in Amirian *et al.*[46]. Cases and controls were genotyped using the Illumina Oncoarray according to the manufacturer's recommendations (Illumina Inc.). Individuals with a call rate <99%, as well as all individuals evaluated to be of non-European ancestry (<80% estimated European ancestry using the FastPop[47] procedure developed by the GAMEON consortium with HapMap version 2 CEU, JPT/CHB and YRI populations as a reference; Supplementary Fig. 5), were excluded. For pairs of apparent first-degree relatives, we removed the control from a case–control pair; otherwise, we excluded the individual with the lower call rate. SNPs with a call rate <95% were excluded as were those with a MAF <0.01 or those displaying significant deviation from the Hardy–Weinberg equilibrium (HWE) (i.e., $P < 10^{-5}$). After performing these quality-control measures, there were 4,572 cases and 3,286 controls remaining for downstream analyses.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

The UK, French, German, MDA, SFAGS and GliomaScan GWAS of non-overlapping case–control series of Northern European ancestry have been the subject of previous studies. Briefly, the UK GWAS[7, 8, 10] was based on 636 cases (401 males; mean age 46 years) who were ascertained through the INTERPHONE study[48]. Individuals from the 1958 Birth Cohort ($n = 2{,}930$) served as a source of controls. The French GWAS[7, 10] comprised 1,495 patients with glioma who were ascertained through the Service de Neurologie Mazarin, Groupe Hospitalier Pitié-Salpêtrière Paris. The controls ($n = 1{,}213$) were ascertained from the SU.VI.MAX (Supplementation en Vitamines et MinerauxAntioXydants) study of 12,735 healthy subjects (women aged 35–60 years; men aged 45–60 years)[49]. The German GWAS[10] comprised 880 patients who had undergone surgery for a glioma at the Department of Neurosurgery, University of Bonn Medical Center, between 1996 and 2008. Control subjects were taken from three population studies: KORA (Co-operative Health Research in the Region of Augsburg; $n = 488$)[50]; POPGEN (Population Genetic Cohort; $n = 678$)[51] and the Heinz Nixdorf Recall study ($n = 380$)[52]. Standard quality-control measures were applied to the UK, French and German GWAS and have previously been reported. The MDA GWAS[8] was based on 1,281 cases (786 males; mean age 47 years) who were ascertained through the MD Anderson Cancer Center, Texas, between 1990 and 2008. Individuals from the Cancer Genetic Markers of Susceptibility (CGEMS, $n = 2{,}245$) studies served as controls[53, 54]. Quality-control measures were applied as per the primary GWAS. The UCSF adult glioma case–control study (SFAGS–GWAS) included participants of the San Francisco Bay Area Adult Glioma Study (AGS). Details of subject recruitment for AGS have been reported previously[9, 12, 34, 55, 56]. Briefly, cases were adults (>18 years of age) with newly diagnosed, histologically confirmed glioma. Population-based cases who were diagnosed between 1991 and 2009 (series 1–4) and who were residing in the six San Francisco Bay area counties were ascertained using the Cancer Prevention Institute of California's early-case ascertainment system. Clinic-based cases who were diagnosed between 2002 and 2012 (series 3–5) were recruited from the UCSF Neuro-oncology Clinic, regardless of the place of residence. From 1991 to 2010, population-based controls from the same residential area as the population-based cases were identified using random digit-dialing and were frequency matched to population-based cases for age, gender and ethnicity. Between 2010 and 2012, all controls were selected from the UCSF general medicine phlebotomy clinic. Clinic-based controls were matched to clinic-based glioma cases for age, gender and ethnicity. Consenting participants provided blood, buccal and/or saliva specimens, and information, during in-person or telephone interviews. A total of 677 cases and 3,940 controls (including 3,347 Illumina iControlDB iControls) were used in the current analysis. For the GliomaScan GWAS[13], in addition to the published analysis, we excluded samples from the ATBC (Finnish study) and controls from NSHDS due to exhibiting outlying population ancestry after manual inspection of PCA plots. In total 1,653 cases and 2,725 controls were used in the current study.

GWAS data from the seven studies were imputed to >10 million SNPs with IMPUTE2 (v2.3)[57] software using a merged reference panel consisting of data from the 1000 Genomes Project (phase 1 integrated release 3, March 2012)[58] and UK10K (ALSPAC, EGAS00001000090 and EGAD00001000195, and TwinsUK EGAS00001000108 and EGAS00001000194 studies). Genotypes were aligned to the positive strand in both

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

imputation and genotyping. Imputation was conducted separately for each study, and in each the data were pruned to a common set of SNPs between cases and controls before imputation. We set thresholds for imputation quality to retain potential risk variants with MAF > 0.01. Poorly imputed SNPs, defined by an information measure <0.40 with IMPUTE2, were excluded, as were SNPs exhibiting a significant deviation from Hardy–Weinberg equilibrium ($P < 1 \times 10^{-8}$) in controls. Test of association between imputed SNPs and glioma was performed using SNPTEST (v2.5)[59] under an additive frequentist model. The adequacy of the case–control matching and the possibility of differential genotyping of cases and controls were formally evaluated using Q-Q plots of test statistics (Supplementary Fig. 1). Where appropriate, principal components, generated using common SNPs, were included in the analysis to limit the effects of cryptic population stratification that otherwise might cause inflation of test statistics. Principal components, based on genotyped SNPs, were generated for the GICC, GliomaScan, MDA-GWAS and SFAGS studies using PLINK[60]. Eigenvectors for the German GWAS were inferred using smartpca (part of EIGENSOFTv2.4)[61] by merging cases and controls with Phase II HapMap samples[10]. PCA plots for all studies are provided in Supplementary Figure 4.

UCSF-Mayo GWAS—The UCSF-Mayo study comprised Mayo cases ($n = 945$) and UCSF cases ($n = 574$) and Mayo Clinic Biobank control ($n = 806$) data. The Mayo Clinic case–control study has been described previously[9, 34, 62]. Briefly, adult cases (>18 years of age) were identified at diagnosis (diagnosed at Mayo Clinic) or at pathologic confirmation (diagnosed elsewhere and treated at Mayo Clinic), and the patients had a surgical resection or biopsy between 1973 and 2014. Consenting participants provided blood, buccal and/or saliva specimens, and information, during in-person or telephone interviews. This analysis used 574 non-overlapping cases from the UCSF Adult Glioma Study described above. Mayo Clinic and UCSF cases were genotyped using the Illumina Oncoarray. The Mayo Clinic Biobank controls comprised volunteers who donated biological specimens and provided risk factor data, access to clinical data obtained from the medical record and consent to participate in any study approved by the Access Committee. Recruitment for the Mayo Clinic Biobank took place from April 2009 through December 2015. Although participants could be unselected volunteers, the vast majority of participants were contacted as part of a pre-scheduled medical examination in the Department of Medicine, Divisions of Community Internal Medicine, Family Medicine and General Internal Medicine at Mayo Clinic sites in Rochester (Minnesota), Jacksonville (Florida), and the Mayo Clinic Health System sites in La Crosse and Onalaska (Wisconsin). All individuals were aged 18 years and older at the time of consent. Illumina Omni Express genotyping arrays were run on the 806 Mayo Clinic Biobank participants.

Quality-control analyses were performed on each cohort separately (Mayo cases, UCSF cases and Mayo Clinic Biobank controls). SNPs with call rates <95% were removed, followed by removal of subjects with call rates <95%. Concordance of replicate samples was assessed, and the sample with the higher call rate was retained. Subject's sex was verified using the sex check option in PLINK. Relationship checking was performed by estimating the proportion of alleles shared identical by descent (IBD) for all pairs of subjects in PLINK[60]. STRUCTURE[63] was used to assess population admixture with 1000 Genomes as

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

a reference. Subjects indicated to be non-Caucasian were excluded. Prior to imputation, SNPs were tested for HWE, and SNPs with HWE $P < 10^{-6}$ were removed. Mayo Clinic, UCSF and Mayo Clinic Biobank SNP data were each phased and imputed using the Michigan Imputation Server with the Haplotype Reference Consortium (release 1; http://www.haplotype-reference-consortium.org) as reference. Genotypes were forward-strand-aligned to the 1000 Genomes reference, and for ambiguous SNPs the Browning strand checking utility was used (http://faculty.washington.edu/sguy/beagle/strand_switching/strand_switching.html). PCA was used to correct for population stratification using SNPs common to cases and controls. The first three principal components were significantly ($P <$ 0.05) associated with case–control status. An additive logistic regression model was used to assess the association between each SNP and disease status, with genotype being coded as 0, 1 or 2 copies of the minor allele, adjusted for age, sex and the first three principal components.

Meta-analysis and additional statistical analyses

Meta-analyses were performed using the fixed-effects inverse-variance method based on the β-esti-mates and standard errors from each study using META (v1.6)[64]. Cochran's Q-statistic was used to test for heterogeneity, and the I^2 statistic was used to quantify the proportion of the total variation due to heterogeneity[65], taking I^2 values >75 to indicate significant heterogeneity. Using the meta-analysis summary statistics and LD correlations from a reference panel of the 1000 Genomes Project combined with UK10K, we used GCTA[66, 67] to perform conditional association analysis. Association statistics were calculated for all SNPs, conditioning on the top SNP in each locus showing genome-wide significance. This was carried out in a step-wise fashion. We performed a case-only analysis to test for differences in SNP-risk-allele frequency between GBM and non-GBM tumors.

ENCODE and chromatin state dynamics

Risk SNPs and their proxies (i.e., $r^2 > 0.8$ in the 1000 Genomes EUR reference panel) were annotated for putative functional effect using HaploReg (v4)[68], RegulomeDB[69] and SeattleSeq Annotation[70]. These servers make use of data from ENCODE, genomic evolutionary rate profiling (GERP) conservation metrics, combined annotation-dependent depletion (CADD) scores and PolyPhen scores. We searched for overlap of associated SNPs with enhancers defined by the FANTOM5 enhancer atlas[19], annotating by overlap with ubiquitous, permissive and robust enhancers, as well as enhancer–promoter correlations and enhancers specifically expressed in astrocytes, neuronal stem cells and brain tissue. Similarly, we searched for overlap with 'super-enhancer' regions, as defined by Hnisz *et al.*[20], restricting analysis to data from U87 GBM cells, astrocyte cells and brain tissue. We additionally made use of 15-state chromHMM data from H1- and H9-derived neuronal progenitor cells available from the Epigenome Roadmap Project[71]. Enhancer enrichment analysis was carried out using HaploReg (v4.0)[68]. Briefly, from a query list of variants, the overlap with enhancers in each of 107 cell types, as predicted from the Roadmap Epigenomics Project[71] chromatin-state segmentations, was calculated. A binomial test for enrichment was performed against a background set of all (i) 1000 Genomes variants with MAF > 0.05 and (ii) all unique GWAS loci in the European population. We applied a cutoff of $P < 3.94 \times 10^{-4}$ corresponding to a Bonferroni correction for 127 cell lines and tissues.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Expression quantitative trait loci (eQTL) analysis

To examine the relationship between SNP genotype and gene expression, we carried out summary-data-based mendelian randomization (SMR) analysis as per Zhu *et al.*[18] (at http://cnsgenomics.com/software/smr/index.html). We used publicly available brain tissue data from the GTEx[16] (http://www.gtexportal.org) v6p release. Briefly, GWAS summary statistics files were generated from the meta-analysis. Reference files were generated from merging 1000 Genomes phase 3 and UK10K (ALSPAC and TwinsUK) vcfs. Summary eQTL files for GTEx samples were generated from downloaded v6p "all_snpgene_pairs" files. Besd files were generated from these summary eQTL files using the –make-besd command. Additionally, we analyzed downloaded whole-blood eQTL data from Westra *et al.*[17]. Results from the SMR test for each of the 13 new glioma loci are reported in Supplementary Data 3. As previously advocated[18], only probes with at least one eQTL P value $<5.0 \times 10^{-8}$ were considered for SMR analysis. We set a threshold for the SMR test of $P_{SMR} < 1.06 \times 10^{-4}$ corresponding to a Bonferroni correction for 473 tests (473 probes with a top eQTL $P < 5.0 \times 10^{-8}$ across the 13 loci, 10 brain regions and Westra data set). For all genes passing this threshold, we generated plots of the eQTL and GWAS associations at the locus, as well as plots of GWAS and eQTL effect sizes (i.e., corresponding to input for the HEIDI heterogeneity test). HEIDI test P values <0.05 were taken to indicate significant heterogeneity. Respective SMR plots for significant eQTLs are shown in Supplementary Figure 4.

Additional statistical and bioinformatics analysis

Estimates of individual variance in risk associated with glioma risk SNPs was carried out using the method described in Pharoah *et al.*[72], assuming the familial risk of high-grade and low-grade glioma to be 1.76 and 1.54, respectively, from analysis of the Swedish series in Scheurer *et al.*[73]. Briefly, for a single allele (i) of frequency p, relative risk R and ln risk r, the variance (V_i) of the risk distribution due to that allele is given by:

$$V_i=(1-p)^2E^2+2p(1-p)(r-E)^2+p^2(2r-E)^2$$

Where E is the expected value of r given by:

$$E=2p(1-p)r+2p^2r$$

For multiple risk alleles, the distribution of risk in the population tends toward the normal with variance:

$$V=\sum V_i$$

The total genetic variance (V) for all susceptibility alleles has been estimated to be √1.77. Thus, the fraction of the genetic risk explained by a single allele is given by:

$$V_i/V$$

LD metrics were calculated in vcftools (v0.1.12b)[74] using UK10K data and plotted using visPIG[75]. LD blocks were defined on the basis of HapMap recombination rate (cM/Mb), as defined using the Oxford recombination hotspots and on the basis of distribution of confidence intervals defined by Gabriel *et al.*[76].

Data availability

Genotype data from the GICC GWAS are available from the database of Genotypes and Phenotypes (dbGaP) under accession phs001319.v1.p1. Additionally, genotypes from the GliomaScan GWAS can be accessed through dbGaP accession phs000652.v1.p1. Data from the other studies are available upon request.

Supplementary Material

Acknowledgments

We are grateful to all of the patients and individuals for their participation, and we would also like to thank the clinicians and other hospital staff members, cancer registries and the study staff members in the respective centers who contributed to the blood sample and data collection.

The GICC was supported by grants from the US National Institutes of Health (NIH) (R01CA139020 (M.L.B. and B.S.M.), R01CA52689 (M.R.W.), R01CA52689 (M.L.B.) and P30CA125123 (M. Scheurer). Additional support was provided by the McNair Medical Institute (M. Scheurer) and the Population Sciences Biorepository at Baylor College of Medicine (M. Scheurer).

In Sweden, work was additionally supported by Acta Oncologica through the Royal Swedish Academy of Science (B.S.M.’s salary) and by the Swedish Research Council (B.S.M.) and the Swedish Cancer Foundation (B.S.M.). We are grateful to the National Clinical Brain Tumor Group and to all of the clinicians and research nurses throughout Sweden who identified all of the cases.

In the UK, funding was provided by Cancer Research UK (C1298/A8362 supported by the Bobby Moore Fund (R.S.H., B.K. and P.B.), the Wellcome Trust (R.S.H., B.K. and P.B.) and the DJ Fielding Medical Research Trust (R.S.H., B.K. and P.B.). The National Brain Tumor Study is supported by the National Cancer Research Network, and we acknowledge all clinicians and healthcare professionals who contributed to this initiative. The UK INTERPHONE study was supported by the European Union Fifth Framework Program 'Quality of Life and Management of Living Resources' (QLK4-CT-1999-01563) (A.S., M.J.S. and S.J.F.) and the International Union against Cancer (UICC) (A.S., M.J.S. and S.J.F.). The UICC received funds from the Mobile Manufacturers' Forum and the GSM Association. Provision of funds via the UICC was governed by agreements that guaranteed INTERPHONE's scientific independence (http://www.iarc.fr/ENG/Units/RCAd.html), and the views expressed in the paper are not necessarily those of the funders. The UK centers were also supported by the Mobile Telecommunications and Health Research (MTHR) Programme, and the Northern UK Centre (A.S., M.J.S. and S.J.F.) was supported by the Health and Safety Executive, Department of Health and Safety Executive and the UK Network Operators.

In France, funding was provided by the Ligue Nationale Contre le Cancer (J.-Y.D.), the Fondation ARC (M. Sanson), the Institut National du Cancer (INCa; PL046; (M. Sanson)), the French Ministry of Higher Education and Research and the program "Investissements d'avenir" ANR-10-IAIHU-06 (M. Sanson, J.-Y.D., M. Labussière, A.-L.D.S., P.G., K.M., A.I., K.H.-X. and K.L.). This study was additionally supported by a grant from Génome Québec, le Ministère de l'Enseignement supérieur, de la Recherche, de la Science et de la Technologie (MESRST) Québec (M. Lathrop) and McGill University (M. Lathrop).

In Germany, funding was provided to M. Simon and J. Schramm by the Deutsche Forschungsgemeinschaft (Si552, Schr285), the Deutsche Krebshilfe (70-2385-Wi2, 70-3163-Wi3, 10-6262) and BONFOR. Funding for the WTCCC was provided by the Wellcome Trust (076113 and 085475; M. Simon and J. Schramm). The KORA Ausburg studies are supported by grants from the German Federal Ministry of Education and Research (BMBF) and were mainly financed by the Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg. This work was financed by the German National Genome Research Network (NGFN) (S. Schreiber and H.E.-W.) and supported within the Munich Center of Health Sciences (MC Health) as part of LMUinnovativ (S. Schreiber and H.E.-W.). Generation of the German control data was partially supported by a grant of the German Federal Ministry of Education and Research (BMBF) through the Integrated Network IntegraMent (Integrated Understanding of Causes and Mechanisms in Mental Disorders), under the auspices of the e:Med research and funding concept (01ZX1314A) (M.M.N., S. Herms and S. Heilmann). M.M.N. is a member of the DFG-funded Excellence Cluster ImmunoSensation and received support from the Alfried Krupp von Bohlen und Halbach-Stiftung.

For the UK GWAS, we acknowledge the funders, organizations and individuals who contributed to the blood sample and data collection as listed in Hepworth *et al.*[45]. MD Anderson acknowledges the work of P. Adatto, F. Morice, H. Zhang, V. Levin, A.W.K. Yung, M. Gilbert, R. Sawaya, V. Puduvalli, C. Conrad, F. Lang and J. Weinberg from the Brain and Spine Center for the MDA GWAS. For the French study, we are indebted to A. Rahimian (Onconeurotek), A.M. Lekieffre and M. Brandel for help in collecting data and to Y. Marie for database support. For the German study, we are indebted to B. Harzheim (Bonn), S. Ott and A. Müller-Erkwoh (Bonn) for help with the acquisition of clinical data and to R. Mahlberg (Bonn), who provided technical support. The UK study made use of control genotyping data generated by the Wellcome Trust Case–Control Consortium. A full list of the investigators who contributed to the generation of the data is available from http://www.wtccc.org.uk. The MDA GWAS made use of control genotypes from the CGEMS prostate and breast cancer studies. A full list of the investigators who contributed to the generation of the data is available from http://cgems.cancer.gov/. French controls were taken from the SU.VI.MAX study. The German GWAS made use of genotyping data from three population control sources: KORA-gen39, the Heinz-Nixdorf RECALL study and POPGEN. The HNR cohort was established with the support of the Heinz-Nixdorf Foundation. F.D. received support from the BONFOR Programme of the University of Bonn, Germany.

The UCSF Adult Glioma Study was supported by the NIH (grant numbers R01CA52689 (M.R.W. and J.K.W.), P50CA097257 (M.R.W. and J.K.W.), R01CA126831 (J.K.W.) and R01CA139020 (M.R.W.)), the Loglio Collective (M.R.W. and J.K.W.), the National Brain Tumor Foundation (M.R.W.), the Stanley D. Lewis and Virginia S. Lewis Endowed Chair in Brain Tumor Research (M.R.W.), the Robert Magnin Newman Endowed Chair in Neuro-oncology (J.K.W.) and by donations from the families and friends of J. Berardi, H. Glaser, E. Olsen, R.E. Cooper and W. Martinusen. This project also was supported by the National Center for Research Resources and the National Center for Advancing Translational Sciences, NIH, through UCSF–CTSI grant UL1 RR024131 (UCSF CTSI). The contents of this work are solely the responsibility of the authors and do not necessarily represent the official views of the NIH. The collection of cancer incidence data used in this study was supported by the California Department of Public Health as part of the statewide cancer reporting program mandated by California Health and Safety Code section 103885, the National Cancer Institute's Surveillance, Epidemiology and End Results Program under contract HHSN261201000140C (awarded to the Cancer Prevention Institute of California), contract HHSN261201000035C (awarded to the University of Southern California) and contract HHSN261201000034C (awarded to the Public Health Institute), and the Centers for Disease Control and Prevention's National Program of Cancer Registries under agreement # U58DP003862-01 (awarded to the California Department of Public Health).

The ideas and opinions expressed herein are those of the author(s), and endorsement by the State of California Department of Public Health, the National Cancer Institute and the Centers for Disease Control and Prevention, or their contractors and subcontractors, is not intended nor should be inferred. Other significant contributors for the UCSF Adult Glioma Study include M. Berger, P. Bracci, S. Chang, J. Clarke, A. Molinaro, A. Perry, M. Pezmecki, M. Prados, I. Smirnov, T. Tihan, K. Walsh, J. Wiemels and S. Zheng.

At Mayo, the authors wish to acknowledge the study participants and the clinicians and research staff at the participating medical centers, the Mayo Clinic Biobank and Biospecimens Accessioning and Processing Shared Resource (in particular its manager, M. Cicek). Work at the Mayo Clinic beyond the GICC was also supported by the NIH (grants P50CA108961 (B. O'Neill) and P30CA15083 (R. Diasio)), the National Institute of Neurological Disorders and Stroke (grant RC1NS068222Z (R.B.J.)), the Bernie and Edith Waterman Foundation (R.B.J.) and the Ting Tsung and Wei Fong Chao Family Foundation (R.B.J.).

The GliomaScan Consortium comprised (apart from authors listed in the author list): L.E.B. Freeman (Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, Maryland, USA), S. Koutros (Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, Maryland, USA), D. Albanes (Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, Maryland, USA), K. Visvanathan (Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, USA and Johns Hopkins Sidney Kimmel Comprehensive Cancer Center, Baltimore, Maryland, USA), V.L. Stevens (Epidemiology Research Program, American Cancer Society, Atlanta, Georgia, USA), R. Henriksson (Department of Radiation Sciences, Oncology, Umea University, Umea, Sweden), D.S. Michaud (Department of Public Health and Community Medicine, Tufts University Medical School, Boston, Massachusetts, USA), M. Feychting (Unit of Epidemiology, Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden), A. Ahlbom (Unit of Epidemiology, Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden), G.G. Giles (Cancer Epidemiology Centre, Cancer Council of Victoria, Melbourne, Victoria, Australia and Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, University of Melbourne, Melbourne, Victoria, Australia), R. Milne (Cancer Epidemiology Centre, Cancer Council of Victoria, Melbourne, Victoria, Australia and Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, University of Melbourne, Melbourne, Victoria, Australia), R. McKean-Cowdin (Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, California, USA), L. Le Marchand (Cancer Research Center, University of Hawaii, Honolulu, Hawaii, USA), M. Stampfer (Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, USA and Departments of Epidemiology and Nutrition, Harvard School of Public Health, Boston, Massachusetts, USA), A.M. Ruder (National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention, Cincinnati, Ohio, USA), T. Carreon (National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention, Cincinnati, Ohio, USA), G. Hallmans (Department of Public Health and Clinical Medicine/Nutritional Research, Umea University, Umea, Sweden), A. Zeleniuch-Jacquotte (Division of Epidemiology, Department of Environmental Medicine, New York University School of Medicine, New York, New York, USA), J.M. Gaziano (Massachusetts Veteran's Epidemiology, Research and Information Center, Geriatric Research Education and Clinical Center, VA Boston Healthcare System, Boston, Massachusetts, USA), H.D. Sesso (Division of Preventive Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts, USA), M.P. Purdue (Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, Maryland, USA), E. White (Fred Hutchinson Cancer Research Center, Seattle, Washington, USA and Department of Epidemiology, University of Washington, Seattle, Washington, USA) and J. Buring (Division of Preventive Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts, USA).

UK10K data generation and access was organized by the UK10K consortium and funded by the Wellcome Trust.

ABSTRACT

The distinctive and unique features of the avian and mammalian zoonotic pathogen *Chlamydia* (*C.*) *psittaci* include the fulminant course of clinical disease, the remarkably wide host range and the high proportion of latent infections that are not leading to overt disease. Current knowledge on associated diseases is rather poor, even in comparison to other chlamydial agents. In the present paper, we explain and summarize the major findings of a national research network that focused on the elucidation of host–pathogen interactions in vitro and in animal models of *C. psittaci* infection, with the objective of improving our understanding of genomics, pathology, pathophysiology, molecular pathogenesis and immunology and conceiving new approaches to therapy. We discuss new findings on comparative genome analysis, the complexity of pathophysiological interactions and systemic consequences, local immune response, the role of the complement system and antigen presentation pathways in the general context of state-of-the-art knowledge on chlamydial infections in humans and animals and single out relevant research topics to fill remaining knowledge gaps on this important yet somewhat neglected pathogen.

UNCORRECTED PROOF

Introduction

The first definition of *Chlamydia* (*C.*) *psittaci* was formulated in 1968 to distinguish it from *C. trachomatis*, the only other known chlamydial species at that time, and was based on the inability to accumulate glycogen in its inclusions and resistance to sulfadiazine (Page, 1968). More recently, the species was redefined to comprise mainly avian strains, but at the same time assigned to the separate genus *Chlamydophila* (Everett et al., 1999). The latter has been abolished in the meantime (Kuo et al., 2011; Stephens et al., 2009), so that *C. psittaci* is now one of nine accepted members of the recombined genus *Chlamydia*. Two more avian chlamydiae (Sachse et al., 2014) and one Candidatus taxon (Vorimore et al., 2013) were discovered recently and are about to be added to the same genus.

The groundwork for modern chlamydia research was laid in the 1960s and 1970s by the pioneering work of J.W. Moulder, A. Matsumoto, G.P. Manire, T.P. Hatch, P.B. Wyrick and several other scientists, who focused on *C. psittaci* in their studies. By analyzing the structure and chemical composition of isolated *C. psittaci* "particles" (Moulder, 1962) conducted one of the first molecular characterizations of chlamydiae. Based on experiments with *C. psittaci*-infected cells (Matsumoto and Manire, 1970) were the first to provide high-resolution images of chlamydial bodies and to describe effects of antibiotics on their morphology. The groundbreaking studies of Hatch (1975) demonstrated that chlamydiae owe their obligate intracellular mode of reproduction to the requirement for energy intermediates produced by the host cell. Not least, Wyrick and colleagues (1978) were the first to describe structural properties of chlamydial compartments (Narita et al., 1976) and the ability of *C. psittaci* to infect immune cells (Wyrick and Brownridge, 1978).

C. psittaci is the causative agent of psittacosis (sometimes also called ornithosis or parrot fever), the most important animal

chlamydiosis of zoonotic character. This systemic disease can take acute, protracted, chronic or subclinical courses and mainly affects psittacine birds and domestic poultry (Andersen and Vanrompay, 2000; Kaleta and Taday, 2003). Typical symptoms include lethargy, hyperthermia, abnormal excretions, respiratory distress, nasal and ocular discharges, weight loss and reduced egg production. *C. psittaci* infections and ensuing disease outbreaks are economically relevant to the poultry industry and significantly compromise animal welfare (Yin et al., 2013). Recent data also indicate that, in concert with *C. trachomatis*, *C. psittaci* may play a role in human trachoma (Dean et al., 2013).

The zoonotic dimension of avian chlamydiosis is another cause for concern, as cases of bird-to-man transmission are regularly reported in the literature (Gaede et al., 2008; Harkinezhad et al., 2009; Heddema et al., 2006; Laroucau et al., 2009). The fact that the overall number of reported cases remained generally low in the past decades is, to some extent, due to the absence of this pathogen in most routine diagnostic schemes. The symptoms in affected individuals are mainly non-specific and influenza-like, but severe pneumonia, endocarditis and encephalitis are not uncommon (Salisch et al., 1996). While it is generally perceived that the course and severity of disease depend on virulence properties of the *C. psittaci* strain involved, the immune response of the host, as well as transmission route and infectious dose, very little is known in concrete terms about any parameter of host–pathogen interactions. Furthermore, latent infection seems to be more widespread than clinical cases, both among birds and humans. It was shown in several studies in cattle that, in the absence of clinical signs, performance and health parameters of chlamydia carriers were clearly inferior to those of chlamydia-free animals (reviewed in Reinhold et al., 2011b). In this context, frequently observed recurrent infections by chlamydiae might pave the way for chronic disease.

The remarkable variety of clinical manifestations displayed by *C. psittaci* and chlamydial infections in general should, at least in part, be explicable through the distinctive features of the causative agent. *C. psittaci* is an obligately intracellular bacterium with a unique biphasic developmental cycle. It exists in basically two morphological stages, the infectious, but metabolically inactive elementary body (EB) and the non-infectious, but metabolically active reticulate body (RB). In the course of a replication cycle, EBs evolve into RBs in a vacuole-like inclusion of the host cell, where the latter undergo binary fission before transforming back into EBs to start a fresh cycle. The natural development can be halted at the intracellular stage through the action of adverse factors, such as interferon (IFN)-γ exposure, iron or amino acid depletion, and antibiotic treatment (Beatty et al., 1994; Wyrick, 2010). This persistent state is characterized by aberrant (enlarged) morphology of RBs, loss of cultivability and rescue of infectivity upon removal of inducers. In the case of *C. psittaci*, induction of persistence in vitro was accompanied by consistent downregulation of membrane proteins, chlamydial sigma factors, cell division protein and RB–EB differentiation proteins from 24 h post-infection onwards (Goellner et al., 2006). While it is not yet clear whether the host immune response can actually trigger transition of chlamydial bodies into the persistent state, although some evidence seems to suggest it (Borel et al., 2008; Pospischil et al., 2009), these observations provide an explanation for the failure of antibiotic treatment to eliminate chlamydial agents from an infected organism (Reinhold et al., 2011a).

Host preference of *C. psittaci* is an interesting yet largely unexplored topic. As the agent is generally referred to as an avian pathogen, there is still a widely held notion that it occurs only in birds. However, a number of surveys showed that *C. psittaci* can be found frequently in non-avian domestic animals, such as cattle (Kemmerling et al., 2009), sheep (Lenzko et al., 2011), swine (Kauffold et al., 2006; Vanrompay et al., 2004), horses (Szeredi et al., 2005; Theegarten et al., 2008), goats and cats (Pantchev et al., 2010), as well as in wildlife (Hotzel et al., 2004) and laboratory rodents (Henning et al., 2008). Although the role of the agent in these hosts remains to be clarified it seems certain that overt clinical manifestations are rare exceptions. In addition, the virulence to humans of non-avian *C. psittaci* strains appears to be negligible compared to avian isolates, since the reported cases of human psittacosis are usually traced back to contact with an avian source. Nevertheless, no genetic markers to distinguish between avian and non-avian strains have been found in comparative genomic studies (Voigt et al., 2012), nor have any virulence criteria been identified (Read et al., 2013). One can hypothesize from these findings that birds are the original and typical host for *C. psittaci*, while mammals merely act as alternate hosts and any passages of avian strains through non-avian hosts are accompanied by loss of virulence. Apart from these considerations, the factors determining host preference and adaptation of chlamydiae are largely unclear.

Comparative genomics: *C. psittaci* – a typical member of the family Chlamydiaceae with unique features

Second-generation sequencing efforts have led to the completion of more than 100 chlamydial genome sequences encompassing all recognized species, except *C. suis*. For *C. psittaci*, whole-genome sequences of 28 strains have become available so far (http://ftp.ncbi.nlm.nih.gov/genomes/ASSEMBLY_BACTERIA/Chlamydia_psittaci/), covering virtually all serotypes and avian and mammalian hosts (Grinblat-Huse et al., 2011; Schofl et al., 2011; Seth-Smith et al., 2011, 2013; Van Lent et al., 2012; Voigt et al., 2011). This wealth of data allows unprecedented insights in the genomic organization, evolutionary dynamics, and genetic diversity of the species.

Comparative analysis of chlamydial genomes showed a high level of sequence and gene order conservation (shared synteny) across members of the family and, as in other obligate intracellular bacteria, a considerably reduced genome, implying dependency on the host organism for many metabolic capabilities. All sequenced *C. psittaci* strains possess a single chromosome of approximately 1.1 Mb, and a conserved plasmid of ~8 kb containing 7–8 protein-coding sequences (CDS) was reported for 12 strains. A total of 911 core CDS are shared among all currently sequenced *C. psittaci* strains, which is equivalent to about 90% of the genes present in each of these genomes (Read et al., 2013). Among the species of *C. psittaci*, *C. abortus*, *C. pneumoniae*, and *C. trachomatis*, 736 genes are still shared (with a total CDS count ranging from 874 to 1097), which illustrates the degree of conservation across chlamydial genomes (Voigt et al., 2012). In contrast, one of the closest relative of *Chlamydiaceae* for which a genomic sequence is available, *Simkania negevensis*, features a genome of more than twice this size with a chromosome of 2.5 Mb and ~2500 predicted CDSs (Collingro et al., 2011).

Conserved synteny is extremely high among most chlamydial genomes. Major genomic rearrangements are present only between the closely related *C. trachomatis* and *C. muridarum* versus the remainder of the *Chlamydiaceae* (Fig. 1). Major deviations from synteny and/or sequence conservation, however, can be observed in genes encoding inclusion membrane proteins, in the hypervariable region near the predicted replication termination region known as the plasticity zone (PZ), as well as among the family of polymorphic membrane protein (*pmp*) genes (Fig. 1). These regions are assumed to harbor key genomic correlates to species-specific adaptation (see also Section "Host adaptation of *C. psittaci*: Escape from the avian innate immune response") to environmental niches, tissue tropism and differences in virulence and pathogenicity (Thomson et al., 2005).

UNCORRECTED PROOF

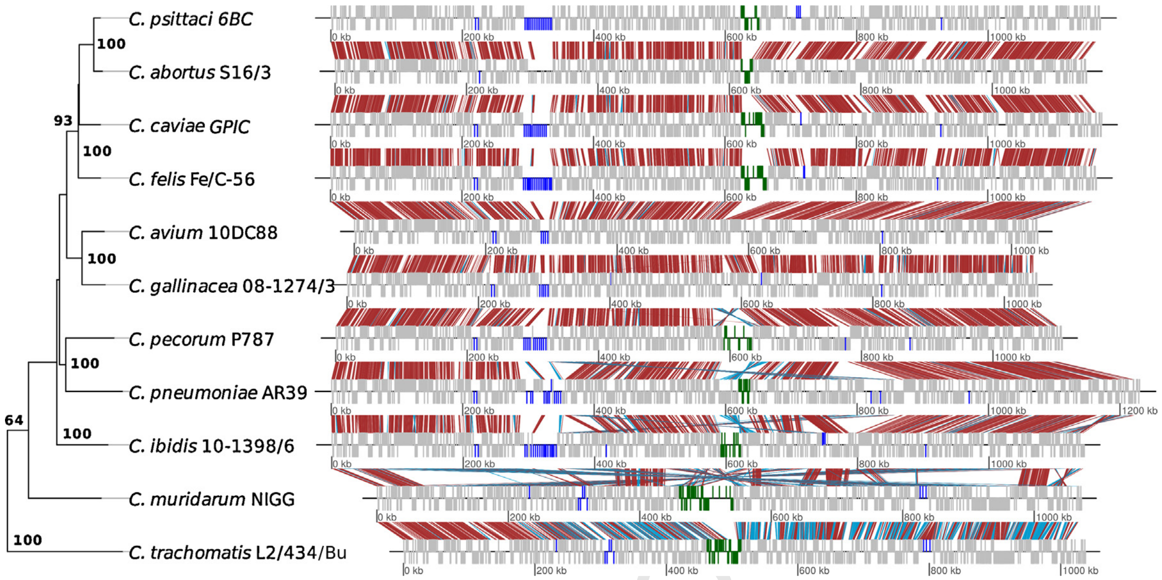

Fig. 1. Comparative genomics. Maximum-likelihood tree based on a random sample of 100 conserved orthologous genes and global comparison of synteny among the eleven fully sequenced species of the family *Chlamydiaceae* (*C. ibidis* is a taxon with *Candidatus* status). Gray tick marks above and below the sequence lines represent predicted CDSs on the plus and minus strands of the genomes, respectively. Color-marked are (blue) members of the polymorphic membrane protein (Pmp) family and (green) genes within the chlamydial plasticity zone (PZ). Red lines connecting genomes represent direct orthologous matches based on best reciprocal BLAT hits; blue lines represent reverse-complemented matches. Bootstrap values are based on 1000 resampled trees.

The size and organization of the PZ differs substantially among *Chlamydiaceae*, ranging from 45 genes in *C. trachomatis* to six genes in koala strain LPCoLN of *C. pneumonia* (Voigt et al., 2012). The PZ of *C. psittaci* is remarkable for its inclusion of a large intact toxin/adhesin gene similar to the EHEC adherence factor, as well as a *guaAB-add* cluster, which plays a role in salvaging biosynthesis of purine nucleotides necessary for bacterial growth. These genes are shared with *C. caviae* and *C. felis*, but are absent (or predicted to have loss-of-function frameshifts) in other chlamydial species, including the closely related *C. abortus* (Voigt et al., 2012). Interestingly, a recent comparative analysis of 20 *C. psittaci* strains revealed that only a subset of *C. psittaci* strains, the monophyletic"6BC clade", and its closest relatives may have acquired these genes through a single event of horizontal gene transfer, or they may have been lost from or degraded in more basal clades of *C. psittaci* on three independent occasions (Read et al., 2013). The 6BC clade comprises 10 strains including type strain 6BC/30 isolated from a parrot (Grinblat-Huse et al., 2011), and contains strains of both avian and mammalian origin corresponding to serotypes A and B (Read et al., 2013). In contrast, two further clades including serotypes C and D comprise only avian hosts. The 6BC clade shows extremely little internal variability (483 polymorphic nucleotide positions) coupled with a distinct lack of host specificity (Read et al., 2013). Interestingly, significant sequence differences between 6BC and non-6BC clades were observed in the large toxin locus. It is tempting to speculate that these remarkable differences among *C. psittaci* strains may have conferred adaptive advantages that facilitated host range expansion in the 6BC lineage.

In several chlamydial species, including *C. psittaci*, *pmp* genes have undergone a significant proliferation resulting in unusually high levels of mutational change within and across species. The Pmps are a large protein family, probably unique to the chlamydiae, with low overall amino acid similarity, but sharing multiple, often alternating motifs GGA (ILV) and FxxN. They are considered to be important in EB adhesion to host cells, molecular transport, and cell wall-associated functions (Longbottom et al., 1998), and have been identified as a critical factor in chlamydial pathogenesis (Tan et al., 2006). Pmps cluster phylogenetically into six subfamilies and are present in varying numbers ranging from a total of nine genes in *C. trachomatis* and *C. muridarum* to 21 in *C. pneumoniae* and *C. psittaci* (Voigt et al., 2012). Subfamily G/I is the largest and most rapidly evolving representative (Voigt et al., 2012). The tendency to proliferation of G/I family Pmps is especially pronounced in *C. psittaci* and its closest relatives, as well as in *C. pneumoniae*. While there are only two G/I *pmp* genes present in *C. trachomatis* and *C. muridarum*, there are 14 G/I family *pmp* genes present in the *C. psittaci* genome, several of which are unique to this species (Voigt et al., 2012). It has been suggested that the diversity in the *pmp* family of genes may have evolved in response to demands of the host environment, e.g. to escape systemic host response or adapt to multiple host environments (Tan et al., 2006). Thus, the extremely high variability of *pmp* genes in *C. psittaci* may also be related to its broad host spectrum.

While homologous recombination is a fundamental mechanism for genetic diversification in free-living bacteria, it is often thought to be limited in obligate intracellular bacteria, whose lifestyle should rarely allow encounters with sources of foreign DNA. With many genomes from the same species becoming available, it has become possible to apply traditional population genetics methods to whole genomes in order to test predictions as above with high precision. Thus, analysis of a large number of *C. trachomatis* genomes recently provided compelling evidence for relatively frequent homologous recombination in this species, despite the ecological barriers to contact posed by an intracellular lifestyle (Joseph et al., 2012). Similar evolutionary dynamics also play a surprisingly strong role in *C. psittaci*, where recombination events are spread evenly across the genome and were estimated to occur at roughly 1/20th the rate of mutation events. However, although recombination was less frequent than mutation, it accounted for three times more substitutions in a genome, because each recombination event affected several nucleotides at a time (Read et al., 2013). Strikingly, BLAST analysis of predicted recombinant segments indicated that roughly 50% of putative DNA imports derive from *C. abortus* or as-yet unknown/unsampled *C. psittaci* strains. This suggests that there is still substantial diversity in *C. psittaci* to be uncovered at the genome level.

UNCORRECTED PROOF

Please cite this article in press as: Knittler, M.R., et al., *Chlamydia psittaci*: New insights into genomic diversity, clinical pathology, host–pathogen interaction and anti-bacterial immunity. Int. J. Med. Microbiol. (2014), http://dx.doi.org/10.1016/j.ijmm.2014.06.010

Clinical pathology: the course of *C. psittaci* respiratory infection in a natural non-avian host

Animal models closely mimicking the relevant characteristics of human disease are still a key element for evaluating pathophysiological consequences and for understanding the underlying mechanisms of disease pathogenesis. Moreover, a valid animal model is a prerequisite for development and efficacy testing of therapeutics and vaccines.

With respect to research on respiratory *C. psittaci* infections, the bovine species offers a number of advantages stated in detail elsewhere (Reinhold et al., 2012). Morphological peculiarities of the bovine lung, including segmental anatomy and the lack of collateral airways, mirror pathophysiological mechanisms of pulmonary dysfunctions more clearly. The availability of a range of highly sensitive, non-invasive pulmonary function tests known from human medicine and previously validated for calves enables detailed evaluation of nature and scope of pulmonary disorders (Ostermann et al., 2014). Additionally, the body size of calves facilitates repeated sampling of biological specimens (e.g. blood and swabs), and thus follow-up monitoring of clinical and immunological parameters (see also Section "Local immune response: Development and resolution of pulmonary lesions after *C. psittaci* infection of calf and mouse"). A calf model using a bovine *C. psittaci* strain potentially allows detailed monitoring of transmission routes, molecular and physiological processes in the course of infection, as well as evaluation of a strain's virulence. The data obtained should be of interest for researchers in both veterinary and human medicine. In a recent series of infection trials, we were able to demonstrate and verify the essential characteristics of a *C. psittaci* infection in its various manifestations (Ostermann et al., 2013a,b, 2014; Reinhold et al., 2012).

First of all, the severity of disease during the acute phase of infection (Fig. 2A) proved clearly dose dependent. Respiratory and clinical signs, which peaked 2–3 days post-inoculation (dpi), were mild after inoculation of 10^6 inclusion-forming units (ifu) of *C. psittaci* strain DC15 per calf, moderate with doses of 10^7–10^8 ifu and severe for 10^9 ifu. This dose–response relation was highly reproducible in extent and quality of lung lesions, and also reflected in respiratory functions affecting pulmonary gas exchange (Ostermann et al., 2013b; Reinhold et al., 2012). Baseline effects due to chlamydial LPS or cell culture medium were ruled out by using controls that received UV-inactivated chlamydiae or medium, respectively.

Secondly, we were able to reproduce the whole variety of characteristic features that are observed in animals and humans affected by natural chlamydial infections. In the case of calves intrabronchially inoculated with 10^8 ifu/calf, a typical course included initial acute clinical illness (2–3 dpi), which subsided considerably, but not completely, within 10 dpi (Ostermann et al., 2013a). Subsequently, a protracted clinically silent course was indicated by intermittent mild symptoms, fecal pathogen excretion, transient chlamydemia, and slightly elevated levels of monocytes and lipopolysaccharide-binding protein (LBP) in blood. Interestingly, these phenomena were also observed as a consequence of naturally acquired, initially mild infection, as induced in a group of naïve calves (sentinels) that socialized with the acutely diseased animals. Again, this underlines the validity of the present bovine infection model and its potential to emulate the natural circumstances. The fact that neither group of calves completely eliminated the chlamydiae within five weeks after exposure (Ostermann et al., 2013a) is also in line with observations in animal herds, where (permanent or intermittent) carriers of chlamydiae represent a permanent reservoir for recurrent outbreaks of disease (Reinhold et al., 2011b). Under field conditions, even asymptomatic chlamydial infections in cattle herds are known to be associated with numerous negative effects on health and performance including significantly reduced growth rate in calves (Jaeger et al., 2007; Poudel et al., 2012; Reinhold et al., 2008).

Thirdly, the humoral immune response was generally weak (see also Section "Local immune response: Development and resolution of pulmonary lesions after *C. psittaci* infection of calf and mouse"). Only two-thirds of calves experimentally challenged with 10^8 ifu developed specific antibodies against *C. psittaci*as detected by immunoblotting. The onset of the antibody response occurred between 7 and 14 dpi. In sentinels, no humoral immune response was observed (Ostermann et al., 2013a; Reinhold et al., 2012). Although innate and acquired humoral immunity are also critically involved in the clearance of chlamydiae, this supports the notion that the cellular immune response plays a central role in controlling anti-bacterial immunity in infected hosts (see also Section "The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens") and also imposes basic constraints on disease control approaches based solely on classical immunoprophylaxis.

Fourthly, the pathological manifestations of acute respiratory *C. psittaci* infection included inflammatory cells (mainly neutrophil granulocytes) recruited onto the site of infection (Figs. 2B and 3B; see also Sections "Local immune response: Development and resolution of pulmonary lesions after *C. psittaci* infection of calf and mouse" and "The innate immune response and its interaction with the adaptive response: Chlamydial infection and the complement system"). Pulmonary inflammation resulted in damage of the alveolar-capillary barrier, as indicated by altered cytology, elevated concentrations of eicosanoids and total protein in broncho-alveolar lavage fluid (Reinhold et al., 2012). Inflammation and the accumulation of detritus and protein-rich fluid caused (i) ventilatory disorders due to both airway obstructions and pulmonary restrictions and (ii) inhibited pulmonary gas exchange. Among the resulting functional consequences were reduced alveolar ventilation (hypoventilation) and reduced oxygen supply to the blood (hypoxemia). Attempts of compensation included the elevation of both respiratory rate and minute ventilation, clinically visible as dyspnea (Ostermann et al., 2013b, 2014).

Pulmonary dysfunctions were accompanied by metabolic disorders in the acid–base equilibrium revealing additional systemic consequences of an acute *C. psittaci* infection on blood pH and blood homeostasis in the host (Ostermann et al., 2014).

Taken together, the bovine model of respiratory *C. psittaci* infection revealed unprecedented insights into the very complex interactions between pathological changes, pathophysiological consequences and clinical signs induced by this pathogen in the mammalian host (Fig. 2B). With respect to comparative and translational medicine, this model builds a useful bridge between basic molecular research and clinical work in patients, both humans and animals. The elucidated host–pathogen interactions provide a suitable basis for further research focusing on new strategies to control this infection through treatment or vaccination.

Local immune response: development and resolution of pulmonary lesions after *C. psittaci* infection of calf and mouse

In recent studies, pulmonary lesions were investigated in models of experimental aerogenous infection with *C. psittaci* in calves (see Section "Clinical pathology: The course of *C. psittaci* respiratory infection in a natural non-avian host") and mice (see Sections "The innate immune response and its interaction with the adaptive response: Chlamydial infection and the complement system" and "The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens") to investigate

Fig. 2. Respiratory *Chlamydia psittaci* infection: complexity of pathogenetic mechanisms, pathophysiological interactions and systemic consequences in the mammalian host (bovine model). (A) Pulmonary lesions in the bovine lung. The section through a cranial lobe reveals several lobules with fibrinopurulent bronchopneumonia (asterisks) in close association with bronchi (arrows) in a calf 4 days after experimental inoculation with *C. psittaci*. (B) Inoculation of *C. psittaci* resulted in infection and replication of the pathogen in pulmonary epithelial cells and initiated an acute-phase reaction. Pro-inflammatory chemokines activated the inflammation cascade with recruitment and accumulation of phagocytic and reactive immune cells from the blood into the lung. Tissue damage and leakages of the alveolo-capillary membrane enabled a spillover of the pathogen into the bloodstream (chlamydemia). Within the lung, fluid, cells and debris in the alveoli and the interstitial tissue provided a barrier for oxygen transfer leading to oxygen deficiency in arterial blood (hypoxemia). Additional interacting factors induced by inflammatory mediators diminished multiple pulmonary functions. Analysis of respiratory mechanics revealed restriction of pulmonary tissue (i.e. limitations in lung compliance) and airway obstructions, both contributing to a reduction in alveolar ventilation (alveolar hypoventilation). Regarding the breathing pattern, expiration was more impaired than inspiration, which resulted in 'apped air', i.e. larger end-expiratory gas volume in the alveolar spaces due to incomplete deflation of the lung (i.e. increased functional residual capacity; FRC). The latter worsened the already existing alveolar hypoventilation and the already reduced oxygen delivery to the blood. In hypoventilated areas of the lung, the corresponding pulmonary arteries constricted (hypoxic pulmonary vasoconstriction; HPV), and those stiffer blood vessels with increased vascular resistance deteriorated the loss of compliant pulmonary properties. In the less compliant lung, the volume inhalable and exhalable per breath (tidal volume) was reduced. Due to the lack of oxygen in the blood, however, respiration was stimulated resulting in a compensatory increase of the respiratory rate and the volume of minute ventilation. Clinically, short, rapid breathing cycles appeared that were characterized by an increased percentage of dead space ventilation and a reduced percentage of alveolar ventilation. Tissue damage and pulmonary dysfunctions had a strong impact on acid–base equilibrium. While alveolar hypoventilation may result in accumulation of CO_2 in the body (hypercapnia) and a consecutive respiratory acidosis (blood pH ↓), the attempt to compensate hypoxemia by a dramatically intensified respired volume per time (hyperventilation) was associated with a loss of CO_2 (hypocapnia) driving blood pH in the direction of respiratory alkalosis (pH ↑). In addition, the demand of oxygen in peripheral tissues in relation to a reduced oxygen supply by the blood stimulated anaerobe metabolism (increased production of L-lactate and protons), which influenced blood pH in the direction of metabolic acidosis (pH ↓). Additional complex metabolic influences on blood pH are described in Ostermann et al. (2014). In general, numerous acidic effects were counterbalanced by a variety of alkalotic effects influencing the acid–base equilibrium in the host organism in multiple ways. In comparative and translational medicine, this integrated large animal model has fundamentally improved our understanding of pathogenetic mechanisms and complex pathophysiological interactions during respiratory *C. psittaci* infection.

species-specific reaction patterns to *C. psittaci* (Fiegl et al., 2013; Lambertz, 2011; Möhle, 2011; Reinhold et al., 2012).

In calves, intra-tracheal application of viable *C. psittaci* induced pneumonia in all animals inoculated (Fig. 2), but in none of the controls (Reinhold et al., 2012). In addition to the dose-dependent clinical score (see Section "Clinical pathology: The course of *C. psittaci* respiratory infection in a natural non-avian host"), the type of lesions changed with increasing dose of inoculum from purulent to fibrinous to necrotizing. Thus, the type of acute lesions differed distinctly from the interstitial and atypical pneumonia generally

Fig. 3. Pulmonary lesions (A–D) and model of local immune response to Chlamydiae (E). Pulmonary lesions 4 days after experimental inoculation of a calf (A and B) and a mouse (C and D) with *C. psittaci*. Lesions in the calf (A) are characterized by fibrinopurulent exudate and foci of necrosis (N), whereas neutrophilic infiltrates predominate in the mouse (C). Numerous chlamydial inclusions (brown) are present in intra-lesional neutrophils and macrophages of calf (B) and mouse (D). A, C bars = 100 μm. B, D bars = 200 μm. In the model of local immune response to chlamydiae (E), infected alveolar epithelial cells secrete interleukin-8 (IL-8), which is a potent pro-inflammatory cytokine playing a key role in recruitment and activation of neutrophils. Neutrophils produce enzymes and reactive oxygen species to kill bacteria and provide the first line of defense against chlamydiae together with macrophages and dendritic cells (DCs). Binding of conserved pathogen-derived molecules by specific receptors on the cell

UNCORRECTED PROOF

reported in calves and humans (Beeckman and Vanrompay, 2009; Jee et al., 2004).

The time course of infection was followed in inoculated calves from 2 days to 1 month after inoculation (Lambertz, 2011; Möhle, 2011). The pneumonic exudate predominantly consisted of neutrophil granulocytes (see also Sections "Clinical pathology: The course of *C. psittaci* respiratory infection in a natural non-avian host" and "The innate immune response and its interaction with the adaptive response: Chlamydial infection and the complement system") at 2 and 3 dpi. Lesions were most severe at days 3 and 4 pi with fibrinous exudate, areas of necrosis and increasing numbers of alveolar macrophages (Fig. 3A). Chlamydial inclusions were detected initially in alveolar epithelial cells and then increasingly in neutrophil granulocytes and alveolar macrophages especially in areas of necrosis (Fig. 3B). Ultrastructural investigation revealed infection of alveolar epithelial cells, neutrophil granulocytes and alveolar macrophages with *C. psittaci*, but multiplication was seen in alveolar epithelial cells only. At day 7 pi, first signs of regeneration were seen: necrotic pulmonary tissue was demarcated by proliferating alveolar epithelial cells and dense infiltrates of macrophages. The zones of regeneration became confluent at day 10 pi and were infiltrated by dendritic cells (DCs) (see also Section "The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens"), macrophages, T and B lymphocytes and plasma cells. At day 14 pi, the numerous lymphocytes, macrophages, DCs and ectopic lymphoid follicles in the lesions indicated a strong local immune response that caused a marked reduction of the number of chlamydiae. The pulmonary tissue had regenerated one month pi except for a few small foci of fibrous scar tissue. Number and distribution of unorganized immune cells were comparable to control calves, but bronchus-associated lymphoid tissue was more pronounced. The intrapulmonary infection of calves with *C. psittaci* allows a detailed study of the steps hypothesized to be involved in the development and organization of lung damage in animals and humans (Beers and Morrisey, 2011).

For the zoonotic agent *C. psittaci*, knowledge about shedding and potential routes of transmission is important. The detection of *C. psittaci* in nasal mucosa and trachea from 2 to 4 days pi was interpreted as excretion of the pathogen with infected exudate from the lung, since chlamydial inclusions were detected in luminal exudate in the trachea by immunohistochemistry. The excretion was limited to the short time period of severe lesions and to low numbers of chlamydial inclusions in the exudate (Lambertz, 2011). Dissemination of *C. psittaci* from the infected lung to sites that are considered to be preferential targets for chronic chlamydial diseases in humans, e.g. aorta and synovial membranes, was detected by PCR. The lack of tissue reaction in these target tissues argues against an active infection and confirms findings from infection experiments in rabbits with *C. pneumonia* (Gieffers et al., 2004).

In another experimental setting, mice were intranasally inoculated with the same strain of *C. psittaci* that was used in calves (see Sections "The innate immune response and its interaction with the adaptive response: Chlamydial infection and the complement system" and "The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens"). The initial phase of infection was similar in both species. At day 4 pi, differences in reaction of mice versus calves became apparent, i.e. extensive purulent inflammation with increasing numbers of macrophages was found in mice (Fig. 3C), while calves developed severe fibrinous exudation with tissue destruction (Fig. 3A). Large numbers of chlamydiae were associated with neutrophil granulocytes and macrophages in the lesions of both hosts (Fig. 3B and D). The different types of inflammatory lesions resulted in distinct healing processes, i.e. mice developed lymphohistiocytic bronchointerstitial pneumonia, whereas regeneration with alveolar epithelial type 2 cell hyperplasia occurred in calves. Both mounted a massive local immune response that eliminated the chlamydiae (see also Sections "The innate immune response and its interaction with the adaptive response: Chlamydial infection and the complement system" and "The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens").

Based on the morphological findings, the following hypothesis for the pathogenesis of pulmonary *C. psittaci* infection can be suggested (Fig. 3E). There is an initial infection of alveolar epithelial cells with *C. psittaci*. The multiplication of *C. psittaci* is followed by a rapid influx of neutrophil granulocytes most likely mediated by cytokines released from infected cells (see Sections "The innate immune response and its interaction with the adaptive response: Chlamydial infection and the complement system" and "The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens"). These initial steps of the inflammatory reaction are consistent with the "cellular paradigm" in chlamydial infections (Stephens, 2003). Degranulation and decay of neutrophil granulocytes cause extensive species-specific damage of the pulmonary tissue. Progressive elimination of *C. psittaci* by adaptive immune response including DCs (see Section "The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens"), T and B cells and regeneration of the pulmonary tissue follow. These findings go beyond the results from the large number of studies where only lesions at a single time point after their initiation or during their development were described. By focusing not only on the pathogen, but also the host's local immune response, our study allows insights into host–pathogen interactions at the commencement, progression and regression of the infection.

Host–pathogen interaction: identifying the molecular partners on both sides of chlamydial cell infection

During the biphasic developmental cycle replicating bacteria acquire energy and biosynthetic precursors from the infected cell. Chlamydiae are capable of modulating cellular functions, such as apoptotic programs and immune response (see also Sections "The innate immune response and its interaction with the adaptive response: Chlamydial infection and the complement system" and "The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens") (reviewed by Bastidas et al., 2013). Studies on inhibitors of bacterial protein synthesis suggest that modulation of host cell functions requires the activity of specific chlamydial proteins (see also Section "Host adaptation of *C. psittaci*: Escape from the avian innate immune response").

C. trachomatis dramatically rearranges the architecture of the eukaryotic host cell including the Golgi apparatus (GA), localization and appearance of the microtubule-organizing center (MTOC) and polarization of migrating cells (Heuer et al., 2009; Heymann et al., 2013; Johnson et al., 2009; Knowlton et al., 2011). These changes contribute either directly to bacterial growth or have implications on pathogenesis. Currently, it is unknown whether these observed changes are specific for *C. trachomatis* or if zoonotic *Chlamydia* strains including *C. psittaci* can induce similar changes. We have experimentally addressed this question by comparing the GA structure in a human cell culture model infected either with *C. psittaci*

surface of macrophages and DCs activates the production of pro-inflammatory cytokines and chemokines, which help to attract other effector cells to the site of infection. Chlamydia-activated DCs present bacteria-derived antigens to T cells and promote the differentiation of naive T cells to various subtypes of effector CD4+ and CD8+ T cells. CD4+ T helper 1 (Th1) cells secrete IFN-γ, which activates the anti-microbial activity of macrophages and helps B-cell production of chlamydia-specific antibodies, whereas Th2 cells provide help for B-cell production of antibodies.

Fig. 4. Human and zoonotic chlamydial infections result in Golgi fragmentation in human cell lines. (A) HeLa cells were infected with either *C. trachomatis* L2 or *C. psittaci* at MOI 2. At 26 h p.i., cells were fixed and stained for the Golgi matrix protein, GM130 (in green). Cells were counter-stained using DAPI and analyzed at a Zeiss LSM 780. Overlay with a phase contrast is shown. Inclusions are indicated using a red line. Scale bar; 10 μm. (B) HeLa cells were infected with *C. trachomatis* L2 or *C. psittaci* using different MOIs. At 26 hpi, cells were fixed and the GA was visualized by GM130 staining. Golgi elements were then quantified using ImageJ. (C) Intracellular transport and lipid supply of chlamydial inclusion. Chlamydia exploits the host's intracellular trafficking machinery by recruiting the microtubule motor protein dynein to the outer surface of the vacuole (mediated by IncB), which drives the migration of inclusions toward the minus end of microtubules and the microtubule-organizing center (MTOC), where it

Please cite this article in press as: Knittler, M.R., et al., *Chlamydia psittaci*: New insights into genomic diversity, clinical pathology, host–pathogen interaction and anti-bacterial immunity. Int. J. Med. Microbiol. (2014), http://dx.doi.org/10.1016/j.ijmm.2014.06.010

or *C. trachomatis* (Fig. 4). Infections resulted in fragmentation of the GA into smaller Golgi elements, and GM-130-positive Golgi elements were recruited to *C. trachomatis* inclusions. In contrast, *C. psittaci*-infected cells showed GM-130-positive Golgi elements scattered throughout the cytosol with no obvious recruitment to the inclusions (Fig. 4A). Quantification of the number of Golgi elements demonstrated Golgi fragmentation is MOI dependent but more pronounced in the case of *C. psittaci* infections (Fig. 4B). In summary, Golgi fragmentation is a hallmark of human and zoonotic chlamydial infections at least in a human cell culture model but mode of fragmentation and/or trafficking of fragmented Golgi elements differ between species. These differences are likely reflected in divergence of chlamydial effector proteins.

All *Chlamydiaceae* spp. possess genes encoding core components of a Type III Secretion (TTS) apparatus, a protein transport system used by Gram-negative bacteria to translocate proteins into the cytoplasm of the host cell. Therefore, it is commonly accepted that chlamydial effector proteins are targeted by the TTS to the inclusion membrane and that their interaction with host proteins cause the modulation of host cell functions (Peters et al., 2007). Interactions of chlamydial effector proteins with host proteins seem to play a role at all stages of chlamydial development, i.e. from adhesion and internalization of EBs till their exit from the host cell.

An important group of chlamydial effector proteins are the Inc (inclusion) proteins, which share a common secondary structural feature of a bilobed hydrophobic domain. While this hydrophobic domain enables the anchoring of the proteins in the inclusion membrane the cytoplasmic tail is responsible for interaction with host proteins (Dehoux et al., 2011). By direct interaction with host cell proteins, Inc proteins may affect different cell functions including signaling and trafficking. One of the first discovered protein–protein interactions was the association of IncG with mammalian 14-3-3β protein (Scidmore and Hackstadt, 2001), which contributes to circumvention of host cell apoptosis. The Inc protein CP0236 impairs IL-17 signaling via interaction with human Act1 (Wolf et al., 2009). Furthermore, IncD of *C. trachomatis* was shown to interact with the lipid transfer protein CERT (Derre et al., 2011), while another Inc protein, CT229, associated with the GTPase Rab4 (Rzomp et al., 2006). Both interactions may affect trafficking processes of the host cell. Finally, Inc protein CT228 was found to recruit elements of the myosin phosphatase pathway to regulate release mechanisms (Lutter et al., 2013).

In a recent study, we focused on the IncA and IncB proteins of the zoonotic agent *C. psittaci* using yeast two-hybrid screens to search for interacting host proteins that could indicate functions of these proteins. In a first attempt, the interaction between type III-secreted protein IncA of *C. psittaci* and host protein G3BP1 was identified. In GST-pull down and co-immunoprecipitation experiments both in vitro and in vivo interaction between full-length IncA and G3BP1 were shown. G3BP1 harbors a phosphorylation-dependent RNase activity that specifically cleaves the 3′-untranslated region of human *c-myc* mRNA. Using fluorescence microscopy, the localization of G3BP1 near the inclusion membrane of *C. psittaci*-infected Hep-2 cells was demonstrated. Notably, infection of Hep-2 cells with *C. psittaci* and overexpression of IncA in HEK293 cells led to a decrease in c-Myc protein concentration. This effect could be ascribed to the interaction between IncA and G3BP1 since overexpression of an IncA mutant construct disabled to interact with G3BP1 failed to reduce c-Myc concentration. We hypothesize that lowering the host cell c-Myc protein concentration may be part of a strategy employed by *C. psittaci* to avoid apoptosis and scale down host cell proliferation (Borth et al., 2011). Furthermore, it was shown that IncB in early inclusions of *C. psittaci* interacts and co-localizes with components of the dynein complex (data not shown). It is known that within the first few hours of infection, endocytosed *C. trachomatis* EBs are transferred to a perinuclear location corresponding to the MTOC of the host cell using the tubulin–dynein system (Grieshaber et al., 2003). Like *C. trachomatis*, *C. psittaci* also utilizes dynein motor proteins for optimal early development (Escalante-Ochoa et al., 2000). The interplay of IncB of *C. psittaci* with dynein components is the first indication of chlamydial proteins being involved in this transport process and possibly affecting the localization and structural appearance of the MTOC (Heuer et al., 2009) to support bacterial growth in the infected cell.

Host adaptation of *C. psittaci*: Escape from the avian innate immune response

Factors and mechanisms determining host specificity of *Chlamydia* spp. are still largely unknown. In a recent study (Braukmann et al., 2012), *C. psittaci* and *C. abortus* were compared for their invasiveness, virulence, and capability of eliciting an immune response in a chicken embryo model. This system has been used for decades, particularly to culture viruses and intracellular bacteria. As it involves inoculation onto the chorioallantoic membrane (CAM) the model resembles natural infection across epithelial layers. In fact it represents a valuable tool to investigate the innate immune response to chlamydial infection and to identify molecular processes on the pathogen's side in conjunction with the host's response that could explain differences in host adaptation between chlamydial species.

When compared with *C. abortus*, which is closely related but prefers non-avian hosts, *C. psittaci* displayed a significantly better capability of disseminating in host organs and elicited higher macrophage numbers and stronger expression of a sub-set of immune-related proteins. Nevertheless, the immune response patterns to both pathogens were largely similar, with expression of the pro-inflammatory mediators IL-1β, IL-6, IL-8, LITAF, IL-17 and iNOS, as well as IFN-γ, IL-12, IL-18, and TLR4, being significantly upregulated in CAM, liver and spleen of *C. psittaci*- and *C. abortus*-infected embryos. However, significant differences in favor of *C. psittaci* were seen in embryo mortality (Fig. 5) and mRNA expression rates of chlamydial genes, such as *incA*, *groEL* (in CAM, liver, spleen), *cpaf* and *ftsW* (in CAM). It is conceivable that elevated expression levels of the IncA protein would contribute to stabilization of the inclusion where the bacteria are residing (see also Section "Host–pathogen interaction: Identifying the molecular partners on both sides of chlamydial cell infection"). As expression of FtsW is used as an indicator of the pathogen's capability to replicate in the host, elevated mRNA expression rates of this gene could explain the better proliferation of *C. psittaci* throughout the infection. Furthermore, upregulation of the gene encoding the chlamydial heat shock protein GroEL (Hsp60) coincided with the elevated macrophage influx during *C. psittaci* infection. GroEL serves as a chaperone during intracellular development (Zugel and Kaufmann, 1999) and seems to be involved in the induction of immune response during human chlamydial infection, where it co-localizes with infiltrating macrophages (Kol et al., 1999).

Compared to *C. abortus*, *C. psittaci* appeared to be more efficient in actively suppressing the host immune response, which enabled better dissemination in the host. In this context, up-regulation of

UNCORRECTED PROOF

resides in a central perinuclear position to establish its intracellular niche near the Golgi apparatus. Fusion, maturation and maintenance of chlamydial inclusions require clustering around the perinuclear MTOC. During the maturation of inclusions chlamydial effector proteins cause Golgi fragmentation and thereby ensure lipid acquisition and bacterial growth.

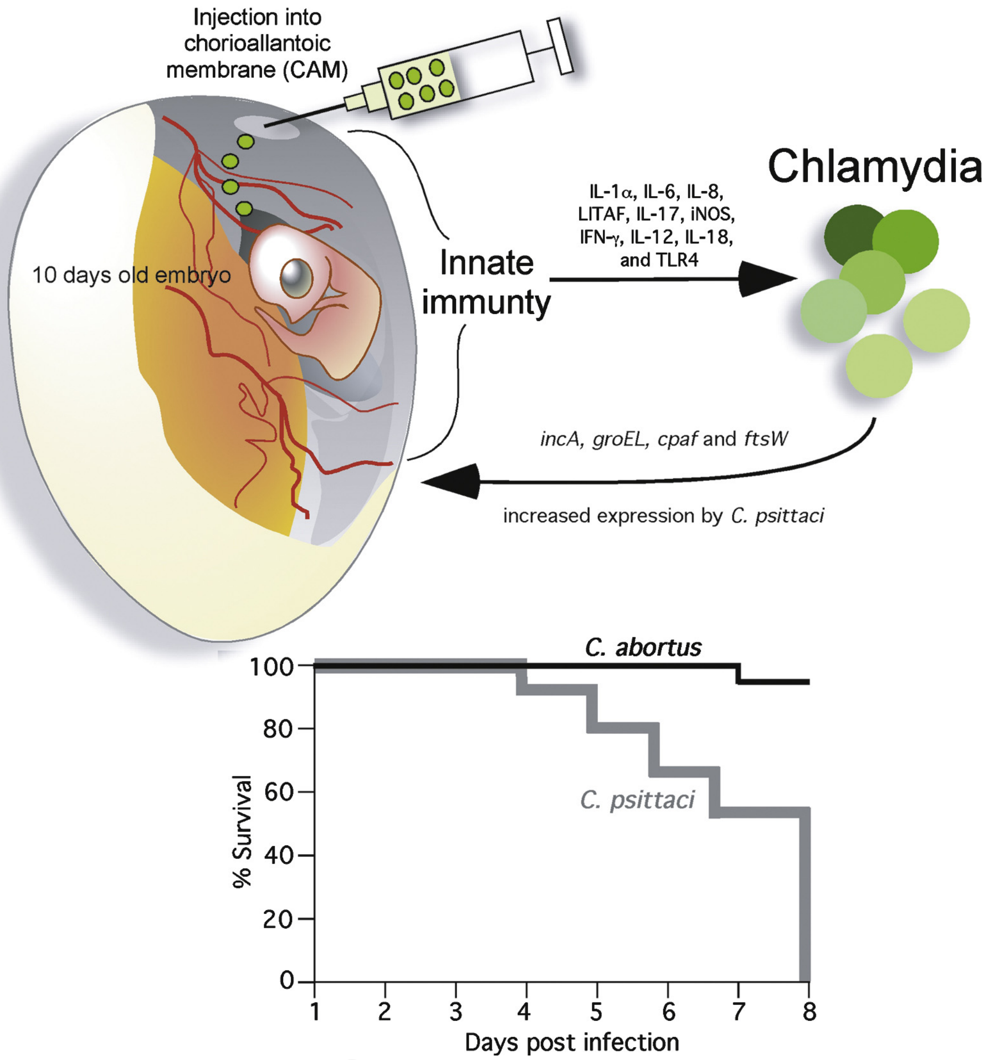

Fig. 5. Chlamydial infection in chicken embryos. Fertilized chicken eggs were incubated at 37.8 °C and a relative humidity of 60%. Inoculation of *C. psittaci* and *C. abortus* was conducted at embryonic developmental day (ED) 10. For infection, the bacterial suspension was transferred onto the chorioallantoic membrane (CAM (upper left panel)). The immune response patterns to both pathogens were largely similar, with expression of the pro-inflammatory mediators (upper right panel). Significant differences in favor of *C. psittaci* were seen mRNA expression rates of essential chlamydial genes (upper right panel), such as *incA*, *groEL*, *cpaf* and *ftsW* and in embryo mortality. Kaplan–Meier curves showing the survival of chicken embryos after infection with *C. psittaci* and, for comparison, *C. abortus* (lower panel). On ED 10, embryos ($n = 20$ per group) were inoculated with comparable amounts of chlamydiae (9×10^4–1×10^5 IFU/egg) and their vitality was determined by daily candling.

cpaf (see also Section “The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens”) probably enabled the pathogen to influence the host reaction in its favor. The results indicate a relevance of *incA* (see also Section “Host-pathogen interaction: Identifying the molecular partners on both sides of chlamydial cell infection”), *groEL*, *cpaf* and *ftsW* for the pathogenicity of *C. psittaci*. The data of the in vivo study provide a basis for a more detailed insight and better understanding of host–pathogen interactions in the course of infection. The fact that *C. psittaci* coped far better than *C. abortus* with the onset of the avian embryo’s innate immune response by upregulating selected genes may be a key to understanding the mechanisms underlying host adaptation and etiopathology.

The innate immune response and its interaction with the adaptive response: Chlamydial infection and the complement system

The complement system consists of approximately 40 serum factors, mainly zymogens, their cleavage products and receptors. It is activated by LPS or lectins and other components of bacterial and viral surfaces. The activated complement system modulates inflammatory responses and protects against extracellular pathogens. Complement is often regarded as a key player of innate immunity (which can additionally be activated by immune complexes). However, there is increasing evidence that it can additionally trigger, enhance and orchestrate adaptive immune responses, at least in viral infections (reviewed by Klos et al., 2013). A complement system with homologous factors and identical function was found not only in mammals, but also in other vertebrate species including birds (Sharma, 1997).

Biologically active cleavage products of the circulating inert complement factors are locally released upon activation. Some of them become part of enzyme complexes, which permit successive steps in the cascade. Others remain soluble, bind to receptors on the host cell surface and act as extracellular mediators for intracellular signaling events. The three classical and broadly known effector functions of the complement cascade, i.e. opsonization via antigen-bound C3b, lysis by the membrane attack complex, pro-inflammation via the anaphylatoxins, are located downstream of complement factor C3. The anaphylatoxic peptides C3a and C5a, cleavage products of factor C3 and factor C5, respectively, activate

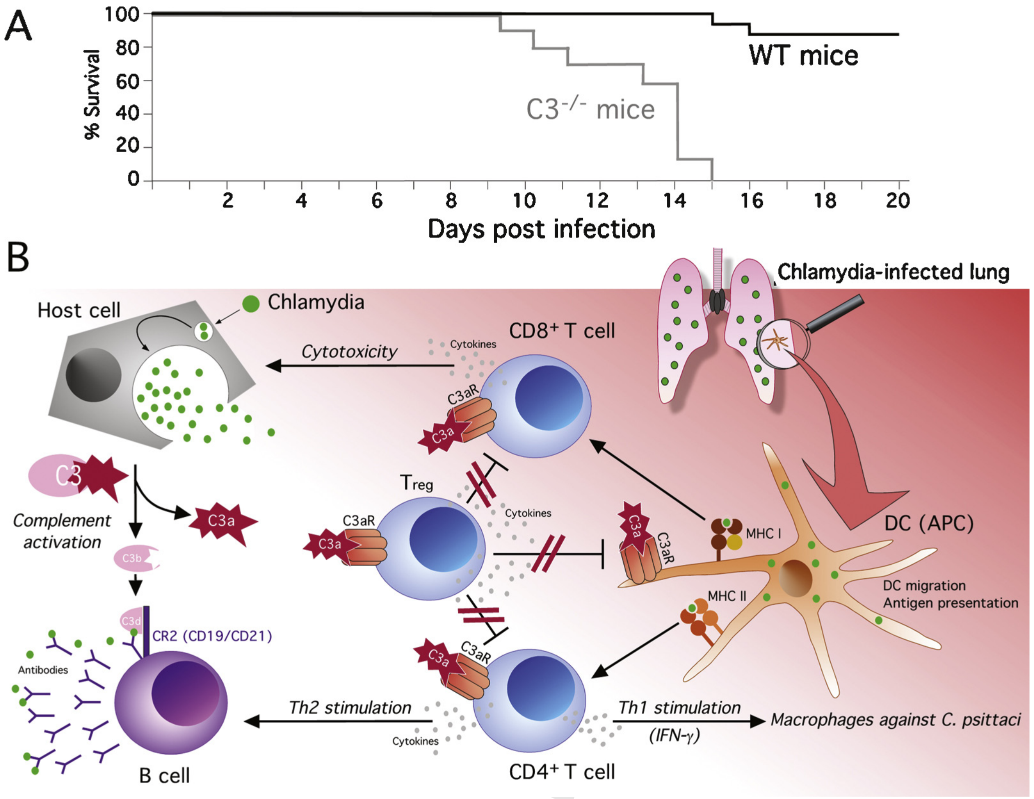

Fig. 6. (A) Complement factor C3 provides protection of mice against *C. psittaci*. $C3^{-/-}$ and the corresponding wild-type (WT) mice were intranasally infected with 10^4 ifu of *C. psittaci* strain DC15. Survival rates were determined for up to 21 days post-infection. (B) Assumed C3a/C3a-receptor (C3aR)-dependent regulation of the adaptive immune response against chlamydiae. Chlamydial elementary bodies (green) activate the complement cascade leading to the cleavage of inactive complement factor C3 into active C3a and C3b. Bound to its antigen, the C3b derivative C3d stimulates via complement receptor 2 (CR2) B cells and antibody production of plasma cells. The C3aR is expressed on mature dendritic cells (DCs) and, most likely, also on various subtypes of activated T cells including $CD4^+$ $CD25^+$ regulatory T cells (Treg cells). For the development of an effective adaptive protection against the bacteria, the immune-modulator C3a stimulates directly $CD4^+$ (Th1 and Th2) and cytotoxic $CD8^+$ T cells. Alternatively, C3aR-signaling down-regulates Treg cells thereby decreasing their inhibition of $CD4^+$ and $CD8^+$ T cells and DCs. Moreover, C3a/C3aR can activate DCs leading to their improved migration to the draining lymph nodes and thus, to an augmented presentation of chlamydial antigens to lymphocytes.

UNCORRECTED PROOF

their G-protein coupled receptors. C3a receptor (C3aR) and C5a receptor (C5aR, $C5a_1$ receptor, CD88) are expressed on cells of myeloic origin including granulocytes, monocytes/macrophages, DCs, mast cells, and even progenitor cells (see also Sections "Local immune response: Development and resolution of pulmonary lesions after *C. psittaci* infection of calf and mouse" and "The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens"). Moreover, the anaphylatoxin receptors are also found on several non-myeloic cells and activated T cells. Albeit C3aR and C5aR are closely related their functions overlap only partially.

EBs of *C. trachomatis* activate complement in vitro thereby reducing their infectivity in cell culture (Fedorko et al., 1987; Lin et al., 1992; Megran et al., 1985). Except for this fact, there was only limited knowledge about the role of complement during infections with *Chlamydia* or other intracellular bacteria at the beginning of the present research project. In a mouse model of intranasal *C. psittaci* lung infection, an early, high and long-lasting activation of the complement system was found (Bode et al., 2012). Intriguingly, only after the first week of infection complement became highly protective with an almost 100-fold increased susceptibility of $C3^{-/-}$ compared to wild type (WT) mice (Fig. 6A). In contrast, there were only minor differences after *C. psittaci* infection of complement factor C5-deficient and $C5aR^{-/-}$ in comparison to WT mice. This indicates that the main protective function of the cascade locates downstream of C3, but upstream of C5. It also points strongly toward C3a/C3aR as promising candidates of combatants for an effective defense against this intracellular microorganism.

Indeed, in our most recent study using $C3aR^{-/-}$ mice, the hypothesis that the C3aR is indispensable for effective protection and improved survival in *C. psittaci* lung infection has been confirmed (Dutow et al., 2013). During the first week, the course of disease was almost identical in infected WT and $C3aR^{-/-}$ mice. However, from then on, the ability to respond via C3aR to C3a significantly shortened severe acute pneumonia, led to drastically higher survival rates, more weight gain and lower clinical score. The bacterial clearance from lung and spleen was impaired in the absence of C3aR. Inflammatory parameters in lung homogenate including several cytokines and neutrophil granulocytes (and myeloperoxidase as granulocyte marker) (see also Section "Local immune response: Development and resolution of pulmonary lesions after *C. psittaci* infection of calf and mouse") remained elevated in $C3aR^{-/-}$ mice, as determined 14 days p.i. The most likely explanation for the sustained inflammatory response is the ongoing *C. psittaci* infection and the higher bacterial burden in the absence of C3aR.

Furthermore, the most likely reason for the impaired clearance of chlamydiae and the high lethality of the $C3aR^{-/-}$ mice during the second and third weeks p.i. has been addressed The time course suggested C3a/C3aR-dependent effects on the adaptive immune response. Indeed, the size of the lung-draining lymph nodes of $C3aR^{-/-}$ mice increased less during chlamydial infection until day 9, i.e. the last time point before $C3^{-/-}$ and $C3aR^{-/-}$ animals can no longer control chlamydial infection and start to die. Intriguingly, cellular and adaptive immune responses were impaired in the absence of C3aR. The numbers of $CD4^+$ T cells and of re-stimulated chlamydia-specific IFN-γ^+ $CD4^+$ and $CD8^+$ cells in lung-draining

Please cite this article in press as: Knittler, M.R., et al., *Chlamydia psittaci*: New insights into genomic diversity, clinical pathology, host–pathogen interaction and anti-bacterial immunity. Int. J. Med. Microbiol. (2014), http://dx.doi.org/10.1016/j.ijmm.2014.06.010

UNCORRECTED PROOF

lymph nodes were smaller; and there was no significant increase in B cells during infection. Following the same line, C3aR$^{-/-}$ mice were largely incapable of chlamydia-specific IgM or IgG production. To address causality and mechanism of C3aR-dependent protection in regard to the diminished antibody response, a serum transfer experiment was performed. Transfer of hyperimmune serum before infection could partially reverse the lethal outcome in C3aR$^{-/-}$ mice, indicating that antibody responses participate in protection against *C. psittaci* re-infection. This is in agreement with earlier reports, which indicated antibody-mediated protection in *C. trachomatis* and *C. muridarum* reinfections, suggesting a general function of antibodies in protection against secondary chlamydial infections (Morrison and Morrison, 2005; Su et al., 1997).

In contrast, transfer of *C. psittaci*-specific IgG to C3aR$^{-/-}$ mice on day 7, i.e. during ongoing acute infection, had only a very limited effect on disease progression and did not reduce lethality at all. This indicates that, in addition to the humoral response, other C3a-dependent functions must be critical for recovery and the much better survival rate of WT mice in our model of primary infection. CD4$^+$ and CD8$^+$ T cells each are sufficient for effective defense against *C. pneumoniae*, with IFN-γ as key player (Rothfuchs et al., 2004), suggesting a similar role of these T cell subsets in the defense against *C. psittaci* (see also Section “The cellular immune response: New insights into MHC I-mediated presentation of chlamydial antigens”). Thus, impaired *C. psittaci*-specific CD4$^+$ and cytotoxic CD8$^+$ T cell responses in infected C3aR$^{-/-}$ mice are presently the most likely causal link and explanation for the C3a-dependent protection in primary infection. Regulatory T cells, which suppress functions of both T cells and DCs and which can be downregulated by C3a (and C5a), might also participate in the immune dysfunction observed in the absence of C3aR in our model (for an illustration of the assumed C3aR-dependent regulation of the adaptive immune response against *C. psittaci* and protection, see Fig. 6B).

The studies described in this section showed that complement, and C3a and its receptor in particular, are critical for defense against *C. psittaci* in murine lung infection. However, it appears that the classical effector functions of the complement system are not important in this defense. Intriguingly, it seems as though C3a acts less as a weak pro-inflammatory mediator, but more as a powerful modulator of the adaptive cellular and humoral reactions against *C. psittaci*. Enhancement of specific B and T cell responses upon infection with an intracellular bacterium were identified as hitherto unknown features of complement and C3aR. These new functions might be of general immunological importance beyond chlamydial infections.

The cellular immune response: new insights into MHC I-mediated presentation of chlamydial antigens

It has been speculated that CD8$^+$T cells primed during chlamydia infection may lyse infected cells and deprive the pathogen of its intracellular niche (Balsara and Starnbach, 2007). If lysis of infected cells occurs early enough in the chlamydial developmental cycle, when the majority of organisms are non-infectious RBs, this mechanism could dramatically slow down the spread of infection within the host. In addition to this protective role of CD8$^+$ T cells during infection, there is evidence for the importance of IFN-□ release from activated CD8$^+$ T cells in controlling chlamydia infection (Starnbach et al., 1994). The initiation of the adaptive immune response (see also Section “Local immune response: Development and resolution of pulmonary lesions after *C. psittaci* infection of calf and mouse”) requires MHC-mediated antigen presentation (Raghavan et al., 2008). In particular, DCs (see also Sections “Local immune response: Development and resolution of pulmonary lesions after *C. psittaci* infection of calf and mouse” and “The innate immune response and its interaction with the adaptive response: Chlamydial infection and the complement system”) are equipped with a specialized machinery that promotes effective display of MHC/peptide complexes, rendering them the most potent stimulators of T lymphocytes (Thacker and Janssen, 2012). DCs perform a kind of sentinel function due to their ability to process internalized antigens before migration to secondary lymphoid organs, where they stimulate different sets of T cells (Thacker and Janssen, 2012). In the classical MHC I-pathway of antigen presentation, cytosolic antigens are degraded into peptide fragments by the proteasome and transported from the cytosol into the ER lumen by peptide transporter TAP (Raghavan et al., 2008). Peptides are then loaded on newly synthesized MHC I, and these complexes are released from the ER and transported to the cell surface via the Golgi (Peaper and Cresswell, 2008). DCs, however, have developed the ability to efficiently present peptides derived from endo- as well as exogenous antigens on MHC I via a process called cross-presentation (Neefjes and Sadaka, 2012). DCs are among the first professional antigen presenting cells (APCs) that are encountered by chlamydiae during infection (Gervassi et al., 2004) (see also Section “Local immune response: Development and resolution of pulmonary lesions after *C. psittaci* infection of calf and mouse”). It is thought that T cells primed by infected DCs play an important role in the effective immune response against chlamydia infection (Ojcius et al., 1998). The strategies used by the mammalian adaptive immune system (e.g. human and murine) are also mirrored in other jawed vertebrates, such as birds, so that, generally speaking, the avian innate and adaptive immune systems strongly resemble those of mammals (Foster and Berndt, 2013; Rolstad and Fossum, 1990; Sharma, 1997). Notably, pathogen-specific T and B cell responses combating chlamydial (Vanrompay et al., 1999) or other bacterial infections (Carvajal et al., 2008) and providing protection were also observed in birds. Moreover, since the avian immune system is also comprised of B, T, and NK cells, DCs, macrophages, as well as cyto/chemokines, it seems straightforward to speculate that mammals and birds use comparable immune mechanisms to elicit anti-chlamydial immunity.

In recent studies, a mouse model (see also Sections “Local immune response: Development and resolution of pulmonary lesions after *C. psittaci* infection of calf and mouse” and “The innate immune response and its interaction with the adaptive response: Chlamydial infection and the complement system”) was used to analyze cellular and molecular requirements of MHC I-cross presentation of *C. psittaci*-infected myeloid (m)DCs (Fiegl et al., 2013). These DCs display morphological as well as functional maturation, which depend mainly on TLR2 signaling and are characterized by formation of dendritic veils, decreased phagocytic activity, elevated expression of distinct activation/maturation markers, as well as secretion of mDC-specific chemo/cytokines that are associated with optimal antigen presentation to T cells and the clearance of infection (Fiegl et al., 2013). Most interestingly, infected DCs permit only a restricted developmental cycle of chlamydiae. Thus, multiple small inclusions containing predominantly RBs, also at late stages of cell infection, are a typical feature (Fiegl et al., 2013). A controlled survival of chlamydiae in infected DCs might be critical to ensure a broad antigen reservoir allowing sustained and efficient chlamydial antigen presentation. The restricted growth of chlamydiae in DCs is induced by TNF-α that interferes with the developmental cycle. The limited growth of *C. psittaci* in infected DCs is accompanied by retention of the chlamydial protease CPAF (see also Section “Host adaptation of *C. psittaci*: Escape from the avian innate immune response”) within bacterial compartments, structural disintegration of inclusions and autophagosomal degradation of released free cytosolic chlamydiae (Fiegl et al., 2013). CPAF had been postulated to be the main virulence factor of chlamydiae (Shaw et al., 2002). It was proposed that the bacterial protease

Fig. 7. Amphisomal cross-presentation of chlamydial antigens. Chlamydial inclusions formed in infected DCs are characterized by structural disintegration. Cytosolic released bacteria are engulfed by autophagosomes, which are able to fuse with endosomal compartments. Chlamydial antigens are preprocessed in these amphisomes and are then transferred across endo-vacuolar membranes for final processing by the proteasome. Antigenic peptides are reimported by TAP into amphisomal compartments and bound on MHC I derived from endosomal recycling of surface molecules. MHC I successfully loaded with chlamydial antigens is presented on the cell surface to CD8⁺ T cells from which they recycle back to the "loading compartment". Depicted immunofluorescence images show colocalization of chlamydia with different effectors of the host cell defense machinery including small HSPs, GBP1 as well as autophagy markers and the presence of MHC I in cathepsin D-positive compartments.

degraded various host factors relevant for chlamydial intracellular survival and that the cytosolic presence of CPAF played an essential role in maintaining the structural integrity of bacterial inclusions (Jorgensen et al., 2011). However, the findings of a recent study by Chen et al. (2012) have raised significant doubt that the identified host factors represent real substrates for CPAF in infected host cells. These new data exact a re-interpretation of the role of this bacterial enzyme during infection and fresh investigations on any CPAF functions.

By analyzing the stress response of *Chlamydia*-infected DCs, we observed an infection-dependent up-regulation of cytoprotective small HSPs (heat-shock proteins), which are known to interact with the cellular cytoskeleton. This process is accompanied by a pronounced co-localization between the HSPs and chlamydial structures. Further experiments showed that knockdown of small HSPs in infected cells resulted in an increase in the bacterial load of infected cells with intact parasitophorous vacuoles encapsulated by actin ring structures. We suggest that

Please cite this article in press as: Knittler, M.R., et al., *Chlamydia psittaci*: New insights into genomic diversity, clinical pathology, host–pathogen interaction and anti-bacterial immunity. Int. J. Med. Microbiol. (2014), http://dx.doi.org/10.1016/j.ijmm.2014.06.010

the observed effects of infection-induced HSPs are likely due to direct interventions on chlamydial cytoskeleton subversion and in turn structural disintegration of chlamydial compartments. Moreover, our studies revealed up-regulation of the host defense factor GBP1 in chlamydia-infected DCs, which targets cytosolic released chlamydiae to autophagosomes to confer cell-autonomous protection and defense against the pathogen (Fiegl et al., 2013). Autophagy is a fundamental cellular mechanism essentially involved in the degradation of intracellular structures (Huang and Brumell, 2009) and has a protective function against cell-invading microbes. Our results suggest that chlamydiae from disintegrated inclusions are efficiently guided to autophagosomal compartments termed amphisomes, which are in close proximity to the collapsed chlamydial structures (Fiegl et al., 2013).

It was also found that chlamydiae do apparently not interfere with the ability of DCs to present MHC I-bound antigens (Fiegl et al., 2013). Thus, *C. psittaci*-infected mature DCs showed increased expression, surface recycling and presentation of MHC I (Fiegl et al., 2013). The induction of MHC I depends on the presence of TNF-α (Fiegl et al., 2013), which is released by chlamydia-infected DCs in response to TLR2 signaling (Prebeck et al., 2001). Chlamydia-infected DCs are also characterized by increased presence of MHC I and TAP in endosomal compartments containing cathepsin D and S (Fiegl et al., 2013). Both hydrolases are known to function as important downstream-proteases in autolysosomal/amphisomal degradation (Boland et al., 2008; Pan et al., 2012). Inhibition of the two cathepsins in infected DCs has a dramatic influence on the MHC I-mediated stimulation of chlamydia-specific CD8$^+$ T cells suggesting important functions for the MHC I-processing of chlamydial antigens (Fiegl et al., 2013). Cathepsin-generated precursor peptides are thought to require further downstream-trimming for MHC I loading (Fonteneau et al., 2003). In accordance with this idea, we found that the proteasome-inhibition affects functional MHC I-presentation to chlamydia-specific CD8$^+$ T cells, indicating a significant contribution of the proteasome in the generation of chlamydial antigens. It appears that chlamydial antigens are first processed in amphisomal compartments, where cathepsins cleave bacterial proteins into large peptides. After cytosolic re-translocation, predigested peptides are further degraded by the proteasome and are then handled by TAP, which is also critically required for functional processing of chlamydial antigens. On the basis of the work described in this section, we propose a new cross-presentation model in which autophagy constitutes an important pathway promoting proteasome/TAP-dependent MHC I processing of chlamydial antigens (Fig. 7).

Clearance of chlamydiae depends on the ability of CD8$^+$ T cells to recognize epithelial cells, in which the bacteria predominantly replicate (Balsara and Starnbach, 2007) (see also Sections 3 and 4). Our recent studies demonstrate that chlamydia-infected epithelial cells retain their full ability to perform MHC I-mediated antigen presentation in the presence and absence of IFN-γ (Kägebein et al., 2013). One could imagine that, in chlamydia-infected epithelial cells, IFN-γ from activated T cells creates a situation reflecting the above-described scenario for infected DCs. Indeed, our own studies and those of other groups showed that, in infected epithelial cells, IFN-γ restricts chlamydial growth (Kägebein et al., 2013; Morrison, 2003) affects cytoplasmic CPAF translocation (Heuer et al., 2003), and induces autophagic degradation of chlamydiae (Al-Zeer et al., 2009).

Our recent findings on MHC I antigen presentation in chlamydia-infected DCs, epithelial cells and fibroblasts provide important novel insights for the development of such future strategies designed to support and maintain T cell-mediated immune responses against chlamydial infections.

Conclusions and outlook

Morbidity and mortality resulting from chlamydial diseases are of major global significance. The zoonotic potential of *C. psittaci* is an important and ongoing challenge for research and practice in human and veterinary medicine. The German national network on "Zoonotic chlamydiae – Models for chronic and persistent infections in man and animals" addressed distinct interconnected questions relating to chlamydial genomics and pathology, as well as host–pathogen interaction and anti-bacterial immunity. The individual studies of this coordinated research effort revealed

- the plasticity zone of the *C. psittaci* genome harboring key genomic correlates to species-specific adaptation to environmental niches, tissue tropism, virulence and pathogenicity,
- a broadened understanding of the complexity between pathological changes, pathophysiological interactions and the clinical outcome of an acute *C. psittaci* infection in the mammalian lung including the resulting systemic consequences,
- new insights into the early events of anti-chlamydial immune response and tissue regeneration in different hosts,
- significant differences and similarities between molecular factors and mechanisms of individual chlamydial pathogens, which might help to develop future strategies for disease control,
- the experimental basis to unravel the mechanisms underlying immune escape and host adaptation in the course of *C. psittaci* infection,
- a previously unknown important protective function of the complement system, particularly of C3a/C3aR, in *C. psittaci* infection of the lung,
- new insights into the role of C3a/C3aR on the development of an effective adaptive immune response against these (and most likely also other) intracellular bacteria, and
- new intracellular pathways of cell-intrinsic immunity and MHC I-mediated antigen presentation.

Although efficacious antimicrobial therapies exist, vaccination is still considered to be the best approach to reduce the prevalence of chlamydial infections. However, currently, there are no vaccines available against chlamydial infection despite the many efforts that have been made throughout the years. Our findings will not only help to develop innovative intervention and vaccination strategies against chlamydial infections, but also provide comparative data for other infectious agents. Clearly, further intensive research on chlamydial infections is required, especially with regard to treatment of persistent varieties, host-adaptation, co-infection with other intracellular pathogens and bacterial mechanisms of immune evasion.

Acknowledgments

This series of studies was conducted in the framework of the national research network "Zoonotic chlamydiae – Models of chronic and persistent infections in humans and animals", which was financially supported by the Federal Ministry of Education and Research (BMBF) of Germany under grants 01KI0720, 01KI1011D, 01Kl10011F, and 01KI1011G. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript. The authors thank Patrik Bavoil, Baltimore (MD), for his critical reading of the manuscript and helpful discussion.

SUMMARY

Dementia is a major problem of health in developed countries, and a prototypical paradigm of chronic disability, high cost, and social-family burden. Approximately, 10–20% of direct costs in this kind of neuropathology are related to pharmacological treatment, with a moderate responder rate below 30% and questionable cost-effectiveness. Over 200 different genes have been associated with the pathogenesis of dementia. Studies on structural and functional genomics, transcriptomics, proteomics and metabolomics have revealed the paramount importance of these novel technologies for the understanding of pathogenic cascades and the prediction of therapeutic outcomes in dementia. About 10–30% of Western populations are defective in genes of the *CYP* superfamily. The most frequent *CYP2D6* variants in the Iberian peninsula are the *1/*1 (57.84%), *1/*4 (22.78%), *1×N/*1 (6.10%), *4/*4 (2.56%), and *1/*3 (2.01%) genotypes, accounting for more than 80% of the population. The frequency of extensive (EMs), intermediate (IMs), poor (PMs), and ultra-rapid metabolizers (UMs) is about 59.51%, 29,78%, 4.46%, and 6.23%, respectively, in the general population, and 57.76, 31.05%, 5.27%, and 5.90%, respectively, in AD cases. The construction of a genetic map integrating the most prevalent *CYP2D6+CYP2C19+CYP2C9* polymorphic variants in a trigenic cluster yields 82 different haplotype-like profiles, with *1*1-*1*1-*1*1 (25.70%), *1*1-*1*2-*1*2 (10.66%), *1*1-*1*1-*1*1 (10.45%), *1*4-*1*1-*1*1 (8.09%), *1*4-*1*2-*1*1 (4.91%), *1*4-*1*1-*1*2 (4.65%), and *1*1-*1*3-*1*3 (4.33%), as the most frequent genotypes. Only 26.51% of AD patients show a pure 3EM phenotype, 15.29% are 2EM1IM, 2.04% are pure 3IM, 0% are pure 3PM, and 0% are 1UM2PM. EMs and IMs are the best responders, and PMs and UMs are the worst responders to a combination therapy with cholinesterase inhibitors, neuroprotectants, and vasoactive substances. The pharmacogenetic response in AD appears to be dependent upon the networking activity of genes involved in drug metabolism and genes involved in AD pathogenesis (e.g., *APOE*). AD patients harboring the *APOE-4/4* genotypes are the worst responders to conventional antidementia drugs. To achieve a mature discipline of pharmacogenomics in CNS disorders and dementia it would be convenient to accelerate the following processes: (i) to educate physicians and the public on the use of genetic/genomic screening in daily clinical practice; (ii) to standardize genetic testing for major categories of drugs; (iii) to validate pharmacogenomic information according to drug category and pathology; (iv) to regulate ethical, social, and economic issues; and (v) to incorporate pharmacogenomic procedures both to drugs in development and drugs on the market in order to optimize therapeutics.

Introduction

Senile dementia is becoming a major problem of health in developed countries, and the primary cause of disability in the elderly. Alzheimer's disease (AD) is the most frequent form of dementia (50–70%), followed by vascular dementia (30–40%), and mixed dementia (15–20%). These prevalent forms of age-related neurodegeneration affect over 25 million people at present, and probably over 75 million people will be at risk in the next 20–25 years worldwide. The prevalence of dementia increases exponentially from approximately 1% at 60–65 years of age to over 30–35% in people older than 80 years. It is very likely that in those patients older than 75–80 years of age most cases of dementia are mixed in nature (degenerative + vascular), whereas pure AD cases are very rare after 80 years of age. The average annual cost per person with dementia ranges from €10,000 to €40,000, depending upon disease stage and country, with a lifetime cost per patient of more than €150,000. In some countries, approximately 80% of the global costs of dementia (direct + indirect costs) are assumed by the patients and/or their families. About 10–20% of the costs in dementia are attributed to pharmacological treatment, including antidementia drugs, psychotropics (antidepressants, neuroleptics, and anxiolytics), and other drugs currently prescribed in the elderly (antiparkinsonians, anticonvulsants, vasoactive compounds, antiinflammatory drugs, etc.). In addition, during the past 20 years over 300 drugs have been partially or totally developed for AD, with the subsequent costs for the pharmaceutical industry, and only 5 drugs with moderate-to-poor efficacy and questionable cost-effectiveness have been approved in developed countries [1–3].

Genomics of Dementia

The genetic defects identified in AD can be classified into three main categories:

(a) Mendelian or mutational defects in genes directly linked to AD, including (i) 32 mutations in the amyloid beta (Aβ) (ABP) precursor protein (*APP*) gene (21q21)(AD1); (ii) 165 mutations in the presenilin 1 (*PSEN1*) gene (14q24.3)(AD3); and (iii) 12 mutations in the presenilin 2 (*PSEN2*) gene (1q31–q42) (AD4) [4–6]. PSEN1 and PSEN2 are important determinants of γ-secretase activity responsible for proteolytic cleavage of APP and NOTCH receptor proteins. Mendelian mutations are very rare in AD (1:1000). Mutations in exons 16 and 17 of the *APP* gene appear with a frequency of 0.30% and 0.78%, respectively, in AD patients. Similarly, *PSEN1*, *PSEN2*, and microtubule-associated protein Tau (*MAPT*)(17q21.1) mutations are present in less than 2% of the cases. Mutations in these genes confer specific phenotypic profiles to patients with dementia: amyloidogeneic pathology associated with *APP*, *PSEN1* and *PSEN2* mutations; and tauopathy associated with *MATP* mutations, representing the two major pathogenic hypotheses for AD [4,7–9].

(b) Multiple polymorphic risk variants characterized in over 200 different genes can increase neuronal vulnerability to premature death(Table 1) [4]. Among these susceptibility genes, the apolipoprotein E (*APOE*) gene (19q13.2)(AD2) is the most prevalent as a risk factor for AD, especially in those subjects harboring the *APOE-4* allele, whereas carriers of the *APOE-2* allele might be protected against dementia [4]. APOE-related pathogenic mechanisms are also associated with brain aging and with the neuropathological hallmarks of AD. Other genes of this category are included in Table 1.

One of the newest members of the AD-gene family is *SORL1*, a gene which encodes a mosaic protein with a domain structure which suggests it is a member of both the vacuolar protein sorting-10 (Vps10) domain-containing receptor family and the low density lipoprotein receptor (LDLR). Inherited variants of the SORL1 neuronal sorting receptor are associated with late-onset AD. Polymorphisms in two different clusters of intronic sequences within the *SORL1* gene may regulate tissue-specific expression of SORL1, which directs trafficking of APP into recycling pathways. When SORL1 is underexpressed, APP is sorted into Aβ-generating compartments leading to amyloid accumulation in neuronal tissues [10]. As with many other potential AD-related genes, the association of *SORL1* with AD [10,11] could not be replicated in other studies [12]. Another interesting gene is *DHCR24* (3β-hydroxysterol-δ-24-reductase) or *Seladin-1*, a key element in the cholesterologenic pathway in which the DHCR24 enzyme catalyzes the transformation of desmosterol into cholesterol [13,14]. *Seladin-1* was originally identified as a gene whose expression was downregulated in the AD brain, demonstrating a neuroprotective effect against neurodegeneration. Recent studies indicate that *Seladin-1/DHCR24* is an LXR (liver X nuclear hormone receptor) target gene potentially involved in the regulation of lipid raft formation [13]. Another gene, with potential therapeutic interest as a tau kinase, might be the *GSK3* gene. Analysis of the promoter and all 12 exons revealed that an intronic polymorphism (IVS2-68G>A) occurred at over twice the frequency among patients with frontotemporal dementia (10.8%) and patients with AD (14.6%) than in aged healthy subjects (4.1%). This is the first evidence that a gene known to be involved in tau phosphorylation is associated with risk for primary neurodegenerative dementias [15]. Promoter polymorphisms modulating *HSPA5* expression might also increase susceptibility to AD. Endoplasmic reticulum chaperone heat shock 70 kDa protein 5 (HSPA5/GRP78) is known to be involved in APP metabolism and neuronal death in AD. Of the three major polymorphisms (–415G/A (rs391957), –370C/T (rs17840761), and –180del/G (rs3216733)), the HSPA5-415G/A and –180del/G variants showed significant differences between AD cases and controls. Subjects harboring the –415AA/–180GG genotype or the –415A/–180G allele might be less susceptible to develop AD [16]. The rs5952C and rs1568566T alleles of the *APOD* rs5952T/C and rs1568566C/T variants increase the risk for AD, whereas the rs5952T-rs1568566C haplotype reduces it [17]. ApoD is a lipoprotein-associated glycoprotein which is increased in the hippocampus and CSF of AD patients [17]. *CALHM1* encodes a multipass transmembrane glycoprotein that controls cytosolic Ca^{2+} concentrations and Aβ levels. The *CALHM1* P86L polymorphism (rs2986017) has been associated with AD [18], but this association could not be replicated in other studies.

Harold et al. [19] undertook a two-stage genome-wide association study (GWAS) of AD involving over 16,000 individuals, and found association with SNPs at two loci not previously associated with the disease, at the *CLU* (Clusterine, APOJ) gene (rs11136000) and 5′ to the *PICALM* gene (rs3851179). In another GWAS with patients from France, Belgium, Finland, Italy and Spain, Lambert et al. [20] found association with *CLU* and with the *CR1* gene, encoding the complement component (3b/4b) receptor 1, on chromosome 1 (rs6656401).

(c) Diverse mutations located in mitochondrial DNA (mtDNA) through heteroplasmic transmission can influence aging and oxidative stress conditions, conferring phenotypic heterogeneity [4,21].

Although *APP* and *PSEN* mutations are considered causative factors for AD, the total number of mutations identified in the

APP, *PSEN1*, and *PSEN2* genes account for less than 3% of the cases with AD, clearly indicating that neurodegeneration associated with AD pathogenesis cannot be exclusively attributed to APP/PSEN-related cascades (amyloid hypothesis). Alterations in the ubiquitin–proteasome system and biochemical disarray in the chaperone machinery are alternative and/or complementary pathogenic events potentially leading to defects in protein synthesis, folding, and degradation with subsequent conformational changes, aggregation, and accumulation in cytotoxic deposits [4,22]. A more plausible explanation would seem to be that multiple susceptibility SNPs with a very subtle genetic variation cooperatively contribute, in concert with environmental factors and concomitant CNS vulnerability, to premature neurodegeneration in dementia.

It is also likely that defective functions of genes associated with longevity may influence premature neuronal survival, since neurons are potential pacemakers defining life span in mammals [4,23]. All these genetic factors may interact in genetic networks which are still unknown, leading to a cascade of pathogenic events characterized by abnormal protein processing and misfolding with a subsequent accumulation of abnormal proteins (conformational changes), ubiquitin–proteasome system dysfunction, excitotoxic reactions, oxidative and nitrosative stress, mitochondrial injury, synaptic failure, altered metal homeostasis, dysfunction of axonal and dendritic transport, and chaperone misoperation [4,22–31]. These pathogenic events may exert an additive effect, converging in final pathways leading to premature neuronal death. Some of these mechanisms are common to several neurodegenerative disorders which differ depending upon the gene(s) affected and the involvement of specific genetic networks, together with cerebrovascular factors, epigenetic factors (DNA methylation) and environmental conditions (nutrition, toxicity, social factors, etc.) [4,23,26–32]. The higher the number of genes involved in AD pathogenesis, the earlier the onset of the disease, the faster its clinical course, and the poorer its therapeutic outcome [4,23,26–31].

Functional Genomics

Functional genomics studies have demonstrated the influence of many genes on AD pathogenesis and phenotype expression. The study of genotype–phenotype correlations is essential for the evaluation of the actual impact of specific polymorphic variants of a particular gene on the clinical manifestation of the disease and/or biological markers reflecting the disease condition or different biological states of the individual. It has been demonstrated that mutations in the *APP*, *PSEN1*, *PSEN2*, and *MAPT* genes give rise to well-characterized differential neuropathological and clinical phenotypes of dementia [4–6]. Transgenic animals also reproduce to some extent the neuropathological hallmarks of AD in a sequential manner. The triple transgenic mouse model of AD (3×Tg-AD) harbors 3 AD-related loci: human PS1M146V, human APPswe, and human MAPTP301L. These animals develop both amyloid plaques and NFT-like pathology in a progressive and age-dependent manner in hippocampus, amygdala, and cerebral cortex, the main foci of human AD neuropathology. The evolution of AD-related transgene expression, amyloid deposition, tau phosphorylation, astrogliosis, and microglia activation throughout the hippocampus, entorhinal cortex, primary motor cortex, and amygdala over a 26-month period has been immunohistochemically documented. Intracellular Aβ accumulation is the earliest of AD-related pathologies to be detectable, followed temporally by phospho-tau, extracellular Aβ, and finally paired helical filament and NFT pathology [33]. In the same model, a decrease in neurogenesis directly associated with the presence of amyloid plaques and an increase in the number of Aβ containing neurons in the hippocampus has been demonstrated [34].

Different *APOE* genotypes also confer specific phenotypic profiles to AD patients. Some of these profiles may add risk or benefit when the patients are treated with conventional drugs, and in many instances the clinical phenotype demands the administration of additional drugs, which increase the complexity of therapeutic protocols. From studies designed to define *APOE*-related AD phenotypes [4,22–31,35–41], several confirmed conclusions can be drawn: (i) the age-at-onset is 5–10 years earlier in approximately 80% of AD cases harboring the *APOE-4/4* genotype; (ii) the serum levels of ApoE are lowest in *APOE-4/4*, intermediate in *APOE-3/3* and *APOE-3/4*, and highest in *APOE-2/3* and *APOE-2/4;* (iii) serum cholesterol levels are higher in APOE-4/4 than in the other genotypes; (iv) HDL-cholesterol levels tend to be lower in *APOE-3* homozygotes than in *APOE-4* allele carriers; (v) LDL-cholesterol levels are systematically higher in *APOE-4/4* than in any other genotype; (vi) triglyceride levels are significantly lower in *APOE-4/4*; (vii) nitric oxide levels are slightly lower in *APOE-4/4*; (viii) serum Aβ levels do not differ between *APOE-4/4* and the other most frequent genotypes (*APOE-3/3*, *APOE-3/4*); (ix) blood histamine levels are dramatically reduced in *APOE-4/4* as compared with the other genotypes; (x) brain atrophy is markedly increased in *APOE-4/4>APOE-3/4>APOE-3/3*; (xi) brain mapping activity shows a significant increase in slow wave activity in *APOE-4/4* from early stages of the disease; (xii) brain hemodynamics, as reflected by reduced brain blood flow velocity and increased pulsatility and resistance indices, is significantly worse in *APOE-4/4* (and in *APOE-4* carriers, in general, as compared with *APOE-3* carriers); (xiii) lymphocyte apoptosis is markedly enhanced in *APOE-4* carriers; (xiv) cognitive deterioration is faster in *APOE-4/4* patients than in carriers of any other *APOE* genotype; (xv) occasionally, in approximately 3–8% of the AD cases, the presence of some dementia-related metabolic dysfunctions (e.g., iron, folic acid, vitamin B_{12} deficiencies) accumulate more in *APOE-4* carriers than in *APOE-3* carriers; (xvi) some behavioral disturbances (bizarre behaviors, psychotic symptoms), alterations in circadian rhythm patterns (e.g., sleep disorders), and mood disorders (anxiety, depression) are slightly more frequent in *APOE-4* carriers; (xvii) aortic and systemic atherosclerosis is also more frequent in *APOE-4* carriers; (xviii) liver metabolism and transaminase activity also differ in *APOE-4/4* with respect to other genotypes; (xix) blood pressure (hypertension) and other cardiovascular risk factors also accumulate in *APOE-4*; and (xx) *APOE-4/4* are the poorest responders to conventional drugs. These 20 major phenotypic features clearly illustrate the biological disadvantage of *APOE-4* homozygotes and the potential consequences that these patients may experience when they receive pharmacological treatment [4,9,22–31,35–43].

Therapeutic Strategies in Dementia

Modern therapeutic strategies in AD are addressed to interfering with the main pathogenic mechanisms potentially involved in AD. Major pathogenic events (drug targets) and their respective therapeutic alternatives include the following: genetic defects, β-amyloid deposition, tau-related pathology, apoptosis, neurotransmitter deficits, neurotrophic deficits, neuronal loss, neuroinflammation, oxidative stress, calcium dysmetabolism, neuronal hypometabolism, lipid metabolism dysfunction, cerebrovascular dysfunction, neuronal dysfunction associated with nutritional and/or metabolic deficits, and a miscellany of pathogenic mechanisms potentially manageable with diverse classes of chemicals or biopharmaceuticals [4,22–31,35,36,41]. Since the early 1980s, the neuropharmacology of AD was dominated by the acetylcholinesterase inhibitors, represented by tacrine, donepezil, rivastigmine, and galantamine [2,3,44]. Memantine, a partial NMDA antagonist, was introduced in the 2000s for the treatment of severe dementia [45]; and the first clinical trials with immunotherapy, to reduce amyloid burden in senile plaques, were withdrawn due to severe ADRs [46]. During the past few years no relevant drug candidates have been postulated for the treatment of AD, despite the initial promises of β- and γ-secretase inhibitors [22].

Pharmacogenomics

Pharmacogenomics relates to the application of genomic technologies, such as genotyping, gene sequencing, gene expression, genetic epidemiology, transcriptomics, proteomics, metabolomics, and bioinformatics, to drugs in clinical development and on the market, applying the large-scale systematic approaches of genomics to speed up the discovery of drug response markers, whether they act at the level of drug target, drug metabolism, or disease pathways [23,25,31,35,47].

The potential implications of pharmacogenomics in clinical trials and molecular therapeutics is that a particular disease could be treated according to genomic and biological markers, selecting medications and diseases which are optimized for individual patients or clusters of patients with a similar genomic profile.

The pharmacogenomic outcome depends upon many different determinant factors including (i) genomic profile, (ii) disease phenotype, (iii) concomitant pathology, (iv) genotype–phenotype correlations, (v) nutritional conditions, (vi) age and gender, (vii) pharmacological profile of the drugs, (viii) drug–drug interactions, (ix) gene expression profile, (x) transcriptomic cascade, (xi) proteomic profile, and (xii) metabolomic networking. The dissection and further integration of all these factors is of paramount importance for the assessment of the pharmacogenomic outcome in terms of safety and efficacy. Pharmacogenomic approaches based on genomewide sets of SNPs associated with drug response are now feasible and may offer the potential to personalize therapeutics [25].

Drug metabolism includes phase I reactions (i.e., oxidation, reduction, hydrolysis) and phase II conjugation reactions (i.e., acetylation, glucuronidation, sulphation, and methylation). The principal enzymes with polymorphic variants involved in phase I reactions are the following: CYP3A4/5/7, CYP2E1, CYP2D6, CYP2C19, CYP2C9, CYP2C8, CYP2B6, CYP2A6, CYP1B1, CYP1A1/2, epoxide hydrolase, esterases, NQO1 (NADPH-quinone oxidoreductase), DPD (dihydropyrimidine dehydrogenase), ADH (alcohol dehydrogenase), and ALDH (aldehyde dehydrogenase). Major enzymes involved in phase II reactions include the following: UGTs (uridine 5′-triphosphate glucuronosyl transferases), TPMT (thiopurine methyltransferase), COMT (catechol-O-methyltransferase), HMT (histamine methyl-transferase), STs (sulfotransferases), GST-A (glutathion S-transferase A), GST-P, GST-T, GST-M, NAT2 (N-acetyl transferase), NAT1, and others [22–25].

CYPs in Dementia

In dementia, *CYP* genomics is a very important issue since in practice over 90% of patients with dementia are daily consumers of psychotropics. Furthermore, some acetylcholinesterase inhibitors (the most prescribed antidementia drugs worldwide) are metabolized via CYP enzymes [24,25,39]. CYP2D6, CYP2C19, CYP2C9, and CYP3A4/5 deserve special consideration.

The CYP2D6 enzyme, encoded by a gene that maps on 22q13.1–13.2, catalyzes the oxidative metabolism of over 100 clinically important and commonly prescribed drugs such as cholinesterase inhibitors, antidepressants, neuroleptics, opioids, some β-blockers, class I antiarrhythmics, analgesics, and many other drug categories [48], acting as substrates, inhibitors or inducers with which many other drugs may potentially interact, this leading to the outcome of ADRs. The CYP2D6 locus is highly polymorphic, with over 100 different *CYP2D6* alleles identified in the general population showing deficient (PM), normal (EM), intermediate (IM), or increased enzymatic activity (UM) [49,50]. Most individuals (>80%) are EMs; however, remarkable interethnic differences exist in the frequency of the PM and UM phenotypes among different societies all over the world [23,51,52]. On average, approximately 6.28% of the world population belongs to the PM category. Europeans (7.86%), Polynesians (7.27%), and Africans (6.73%) exhibit the highest rate of PMs, whereas Orientals (0.94%) show the lowest rate. The frequency of PMs among Middle Eastern populations, Asians, and Americans is in the range of 2–3%. *CYP2D6* gene duplications are relatively infrequent among Northern Europeans, but in East Africa the frequency of alleles with duplication of *CYP2D6* is as high as 29% [53].

CYP2D6-Related Therapeutic Response to a Multifactorial Treatment in Dementia

Few prospective clinical trials have been performed to elucidate the influence of *CYP2D6* variants on the therapeutic outcome in AD in response to cholinesterase inhibitors or other antidementia drugs. We have performed the first prospective study in AD patients who received a combination therapy with (a) an endogenous nucleotide and choline donor, CDP-choline (500 mg/day), (b) a nootropic substance, piracetam (1600 mg/day), (c) a vasoactive compound, 1,6 dimethyl 8β-(5-bromonicotinoyl-oxymethyl)-10α-methoxyergoline (nicergoline) (5 mg/day), and (d) a cholinesterase inhibitor, donepezil (5 mg/day), for one year. With this multifactorial therapeutic intervention, EMs improved their cognitive function (MMSE score) from 21.58 ± 9.02 at baseline to 23.78 ± 5.81 after 1-yr treatment. IMs also improved from 21.40 ± 6.28 to 22.50 ± 5.07 ($r = +0.96$), whereas PMs and UMs deteriorate from 20.74 ± 6.72 to 18.07 ± 5.52 ($r = -0.97$), and from 22.65 ± 6.76 to 21.28 ± 7.75 ($r = -0.92$), respectively. According to these results, PMs and UMs were the worst responders, showing a progressive cognitive decline with no therapeutic effect, and EMs and IMs were the best responders, with a clear improvement in cognition after one year of treatment. Among EMs, AD patients harboring the *1/*10 genotype responded better than patients with the *1/*1 genotype. The best responders among IMs were the *1/*3, *1/*6 and *1/*5 genotypes, whereas the *1/*4, *10/*10, and *4/*10 genotypes were poor responders. Among PMs and UMs, the poorest responders were carriers of the *4/*4 and *1×N/*1 genotypes, respectively [4,9,22,25,36–39]. In a recent study, Pilotto et al. [54] have confirmed the influence of *CYP2D6* variants (rs1080985) on the efficacy of donepezil in AD.

From all these data we can conclude the following: (i) The most frequent *CYP2D6* variants in the Southern European population (Iberian peninsula) are the *1/*1 (57.84%), *1/*4 (22.78%), *1×N/*1 (6.10%), *4/*4 (2.56%), and *1/*3 (2.01%) genotypes, accounting for more than 80% of the population; (ii) the frequency of EMs, IMs, PMs, and UMs is about 59.51%, 29,78%, 4.46%, and 6.23%, respectively, in the general population (GP), and 57.76, 31.05%, 5.27%, and 5.90%, respectively in AD cases; (iii) EMs are more prevalent in GP (59.51%) than in AD (57.76%); IMs are more frequent in AD (31.05%) than in GP (29.78%); the

© 2010 Blackwell Publishing Ltd

frequency of PMs is slightly higher in AD (5.27%%) than in GP (4.46%); and UMs are more frequent in GP (6.23%) than in AD (5.90%); (iv) there are differences between females and males in the distribution and frequency of *CYP2D6* genotypes which might be of relevance in therapeutic terms and risk of ADRs; (v) there is an accumulation of AD-related genes of risk in PMs and UMs; (vi) PMs and UMs tend to show higher transaminase activities than EMs and IMs; (vii) EMs and IMs are the best responders, and PMs and UMs are the worst responders to a combination therapy with cholinesterase inhibitors, neuroprotectants, and vasoactive substances; and (viii) the pharmacogenetic response in AD appears to be dependent upon the networking activity of genes involved in drug metabolism and genes involved in AD pathogenesis [4,9,22,24,25,36–39].

CYP Clustering in Alzheimer's disease

Since over half of the available drugs are metabolized via different CYP enzymes and other metabolic pathways, it is convenient to understand the networking activity of *CYP* genes and the genomic profiles of these genes in particular groups of risk. In the case of dementia, 73.71% of AD patients are *CYP2C19*-EMs, 25.12% IMs, and 1.16% PMs. The distribution and frequency of *CYP2C9* genotypes is as follows: *1/*1-EM 60.87%, *1/*2-IM 23.98%, *1/*3-IM 10.17%, *2/*2-PM 2.54%, *2/*3-PM 2.16%, and *3/*3-PM 0.25%, globally representing 60.87% *CYP2C9*-EMs, 34.16% IMs, and 4.97% PMs [23]. This is especially important because the *CYP2C9*-Ile359Leu (*CYP2C9*3* allele) and *CYP2C9*-Arg144Cys (*CYP2C9*2* allele) variants are associated with warfarin sensitivity. Clustering together *CYP2C9* and *VKORC1* variants, we can estimate that approximately 30% of the elderly population is sensitive to warfarin anticoagulants.

Concerning *CYP3A4/5* polymorphisms, 82.75% of AD cases are EMs (*CYP3A5*3/*3*), 15.88% are IMs (*CYP3A5*1/*3*), and 1.37% are UMs (*CYP3A5*1/*1*) [25].

The human *CYP3A* subfamily plays a dominant role in the metabolic elimination of more drugs than any other biotransformation enzyme. CYP3A enzyme is localized in the liver and small intestine and thus contributes to first-pass and systemic metabolism. CYP3A expression varies as much as 40-fold in liver and small intestine donor tissues. Unlike other human P450s (*CYP2D6*, *CYP2C19*) there is no evidence of a 'null' allele for *CYP3A4*. Over 50 SNPs have been identified in the *CYP3A4* gene. The most common variant, *CYP3A4*1B*, is an A-392G transition in the 5′-flanking region with an allele frequency ranging from 0% (Chinese and Japanese) to 45% (African-Americans). *CYP3A5* is polymorphically expressed in adults with readily detectable expression in about 10–20% in Caucasians, 33% in Japanese and 55% in African-Americans. The primary causal mutation for its polymorphic expression (*CYP3A5*3*) confers low CYP3A5 protein expression as a result of improper mRNA splicing and reduced translation of a functional protein. The *CYP3A5*3* allele frequency varies from approximately 50% in African-Americans to 90% in Caucasians. Functionally, microsomes from a *CYP3A5*3/*3* liver contain very low CYP3A5 protein and display on average reduced catalytic activity towards midazolam. Additional intronic or exonic mutations (*CYP3A5*5, *6*, and *7) may alter splicing and result in premature stop codons or exon deletion. As CYP3A5 is the primary extrahepatic CYP3A isoform, its polymorphic expression may be implicated in disease risk and the metabolism of endogenous steroids or xenobiotics [55].

The construction of a genetic map integrating the most prevalent *CYP2D6+CYP2C19+CYP2C9* polymorphic variants in a trigenic cluster yields 82 different haplotype-like profiles. The most frequent trigenic genotypes in the AD population are *1*1-*1*1-*1*1 (25.70%), *1*1-*1*2-*1*2 (10.66%), *1*1-*1*1-*1*1 (10.45%), *1*4-*1*1-*1*1 (8.09%), *1*4-*1*2-*1*1 (4.91%), *1*4-*1*1-*1*2 (4.65%), and *1*1-*1*3-*1*3 (4.33%). These 82 trigenic genotypes represent 36 different pharmacogenetic phenotypes. According to these trigenic clusters, only 26.51% of the patients show a pure 3EM phenotype, 15.29% are 2EM1IM, 2.04% are pure 3IM, 0% are pure 3PM, and 0% are 1UM2PM (the worst possible phenotype) [25].

Pharmacogenomics of AD-Related Genes

APOE- and *ACE*-related pharmacogenomics

The pharmacogenomics of AD is still in a very primitive stage. In over 100 clinical trials for dementia, *APOE* has been used as the only gene of reference for the pharmacogenomics of AD [4,24,25,36–38,56,57]. Several studies indicate that the presence of the *APOE-4* allele differentially affects the quality and extent of drug responsiveness in AD patients treated with cholinergic enhancers (tacrine, donepezil, galantamine, rivastigmine), neuroprotective compounds (nootropics), endogenous nucleotides (CDP-choline), immunotrophins (anapsos), neurotrophic factors (cerebrolysin), rosiglitazone, or combination therapies [4,24,25,36–39,56–58]; however, controversial results are frequently found due to methodological problems, study design, and patient recruitment in clinical trials.

In long-term open clinical trials with a multifactorial treatment, *APOE-4/4* carriers are the worst responders [4,24,25,36–39]. With a similar therapeutic protocol, *PSEN1-1/1* homozygotes are the worst responders and *PSEN1-2/2* carriers are the best responders [25]. Significant *ACE*-related therapeutic responses to multifactorial treatments have also been reported [22,39]. Among *ACE-I/D* variants, *ACE-D/D* patients were the worst responders (r = –0.58), and *ACE-I/D* carriers were the best responders (r = +0.26), with *ACE-I/I* showing an intermediate positive response (r = +0.01) [22,39]. *ACE*-related biochemical and hemodynamic phenotypes have been studied in patients with AD [4,22,23]. *ACE-I/I* patients tend to be younger than *ACE-I/D* or *ACE-D/D* patients at the time of diagnosis and also to show a more severe cognitive deterioration. Serum ApoE, total cholesterol, LDL-cholesterol, HDL-cholesterol, nitric oxide, histamine, and ACE levels are higher in *ACE-I/I* carriers than in patients with the other genotypes; in contrast, serum triglyceride and VLDL levels are notably lower in *ACE-I/I* patients compared to patients harboring the *ACE-I/D* or *ACE-D/D* genotypes, whereas Aβ levels do not show any clear difference among *ACE*-related genotypes. Cerebrovascular function tends to be worse in *ACE-D/D*, with lower brain blood flow velocities and higher pulsatility and resistance indices, than in *ACE-I/D* (intermediate cerebrovascular hemodynamics) or *ACE-I/I* (almost normal cerebrovascular function) [4,22,23,39]. The correlation between lipid levels and brain hemodynamics is very similar in this study to data observed in that of *CYP2D6*-related metabolizer profiles in which EM patients with moderate cholesterol and lipoprotein levels (as well as relatively high nitric oxide, histamine, ACE, and ApoE levels) tend to show a better cerebrovascular hemodynamic profile than AD patients with lower cholesterol and lipoprotein levels [39]. This apparently paradoxical correlation appears to indicate that major influences in cerebrovascular homeostasis and hemodynamic brain blood flow are cholesterol, lipoproteins, nitric oxide, ACE, and histamine, among many other factors, in AD, and that peripheral levels of Aβ are indifferent in this concern. On the other hand, it seems likely that low triglyceride levels may facilitate cerebrovascular function. It is also worth mentioning that *ACE-I/I* patients with the highest cholesterol levels are the worst in mental performance. Other interpretation of these data might suggest an association between poor cerebrovascular function with *ACE-D/D* and *ACE-I/D*, and an association between alterations in lipid metabolism in *ACE-I/I* [22,39].

Both *APOE* and *ACE* variants also affect behavior and the modification of behavioral changes (mood, anxiety) in dementia after nonpsychotropic pharmacological treatment [4,22,24,37,40]. At baseline, all *APOE* variants show similar anxiety and depression rates, except the *APOE-4/4* carriers who differed from the rest in significantly lower rates of anxiety and depression. Remarkable changes in anxiety were found among different *APOE* genotypes. Practically, all *APOE* variants responded with a significant diminution of anxiogenic symptoms, except patients with the *APOE-4/4* genotype who only showed a slight improvement. The best responders were *APOE-2/4* ($r = -0.87$) > *APOE-2/3* ($r = -0.77$) > *APOE-3/3* ($r = -0.69$) > *APOE-3/4* carriers ($r = -0.45$). The potential influence of *APOE* variants on anxiety and cognition in AD does not show a clear parallelism, suggesting that other more complex mechanisms are involved in the onset of anxiety in dementia. Concerning depression, all *APOE* genotypes improved their depressive symptoms with treatment except those with the *APOE-4/4* genotype, which worsen along the treatment period. The best responders were *APOE-2/4* ($r = -0.85$) > *APOE-2/3* ($r = -0.77$) > *APOE-3/3* ($r = -0.73$) > *APOE-3/4* ($r = -0.16$), and the worst responder was *APOE-4/4* ($r = +0.31$) [22,39]. Patients with each one of the 3 *ACE-I/D* indel variants are equally anxiogenic and depressive at baseline and all of them respond favorably to the multifactorial protocol by gradually reducing anxiety and depressive symptoms over the 12-month treatment period. The best responders were *ACE-I/D* ($r = -0.89$) > *ACE-D/D* ($r = -0.68$) > *ACE-I/I* ($r = -0.08$). Depressive symptoms were also similarly improved in all *ACE-I/D* variants. The best responders were *ACE-I/D* ($r = -0.88$) > *ACE-D/D* ($r = -0.55$) > *ACE-I/I* ($r = -0.13$). Comparatively, the worst responders among *ACE-I/D* variants were carriers of the *ACE-I/I* genotype which were also the poorest responders in anxiety and cognition [22,39,41].

The combination of *APOE* and *ACE* polymorphic variants in bigenic clusters yields different anxiety and depression patterns at baseline and after one year of treatment. The most anxiogenic patients at baseline are those with the *23DD*, *44ID*, and *34II* genotypes, and the least anxiogenic patients are those harboring the *23II*, *44DD*, and *23ID* genotypes. The most depressive clusters at baseline are those harboring the *23DD*, *33ID*, and *33II* genotypes, with a clear accumulation of *APOE-3/3* carriers in these groups, and the least depressive clusters are those represented by carriers of the *23II*, *44ID*, and *23ID* genotypes. All bigenic clusters show a positive anxiolytic and anti-depressive response to the multifactorial treatment, except *44DD* carriers who exhibited the worst response [22,39,41].

Influence of *APOE-CYP2D6* interaction on AD pharmacogenomics

APOE influences liver function and CYP2D6-related enzyme activity probably via regulation of hepatic lipid metabolism. It has been observed that APOE may influence liver function and drug metabolism by modifying hepatic steatosis and transaminase activity. There is a clear correlation between APOE-related TG levels and GOT, GPT, and GGT activities in AD [22,39]. Both plasma TG levels and transaminase activity are significantly lower in AD patients harboring the *APOE-4/4* genotype, probably indicating (a) that low TG levels protect against liver steatosis, and (b) that the presence of the *APOE-4* allele influences TG levels, liver steatosis, and transaminase activity. Consequently, it is very likely that APOE influences drug metabolism in the liver through different mechanisms, including interactions with enzymes such as transaminases and/or cytochrome P450-related enzymes encoded in genes of the *CYP* superfamily [22,39,41].

When *APOE* and *CYP2D6* genotypes are integrated in bigenic clusters and the *APOE+CYP2D6*-related therapeutic response to a combination therapy is analyzed in AD patients, it becomes clear that the presence of the *APOE-4/4* genotype is able to convert pure *CYP2D6*1/*1* EMs into full PMs, indicating the existence of a powerful influence of the *APOE-4* homozygous genotype on the drug metabolizing capacity of pure *CYP2D6*-EMs. In addition, a clear accumulation of *APOE-4/4* genotypes is observed among *CYP2D6* PMs and UMs [25].

Conclusions

From these studies we can conclude the following: (i) Most studies with acetylcholinesterase inhibitors indicate that the presence or absence of the *APOE-4* allele influences the therapeutic outcome in patients with AD. (ii) Multifactorial treatments combining neuroprotectants, endogenous nucleotides, nootropic agents, vasoactive substances, cholinesterase inhibitors, and NMDA antagonists associated with metabolic supplementation on an individual basis adapted to the phenotype of the patient may be useful to improve cognition and slow-down disease progression in AD. (iii) The therapeutic response in AD seems to be genotype-specific under different pharmacogenomic conditions. (iv) In monogenic-related studies, patients harboring the *APOE-4/4* genotype are the worst responders. (v) *APP*, *PSEN1* and *PSEN2* mutations influence the therapeutic response in AD. (vi) In trigenic-related studies (*APOE+PSEN1+PSEN2*) the best responders are those patients carrying the *331222–*, *341122–*, *341222–*, and *441112–* genomic clusters. (vii) The worst responders in all genomic clusters are patients with the *441122+* genotype. (viii) The interaction of several AD-related genes seems to be determinant for drug efficacy and safety.

(ix) *APOE-CYP2D6* interactions might influence the therapeutic response in AD via changes in lipid metabolism and liver function. (x) *APOE* may also interact with PSEN1, ACE, A2M, and other genes (e.g., *CETP*, *AGT*, and *NOS3*) to regulate the effect of drugs on cognition and behavioral changes in dementia. (xi) The *APOE-4/4* genotype seems to accelerate neurodegeneration anticipating the onset of the disease by 5–10 years; and in general, *APOE-4/4* carriers show a faster disease progression and a poorer therapeutic response to all available treatments than any other polymorphic variant. (xii) Pharmacogenomic studies using monogenic, bigenic, trigenic, tetragenic or polygenic clusters as a harmonization procedure to reduce genomic heterogeneity in clinical trials are very useful in order to widen the therapeutic scope of limited pharmacological resources [4,22–31,36–41].

Taking into consideration the data available, it might be inferred that at least 10–15% of the AD population may exhibit an abnormal metabolism of cholinesterase inhibitors and/or other drugs, which undergo oxidation via CYP2D6-related enzymes. Approximately 50% of this population cluster would show an ultrarapid metabolism, requiring higher doses of cholinesterase inhibitors in order to reach a therapeutic threshold, whereas the other 50% of the cluster would exhibit a poor metabolism, displaying potential adverse events at low doses. If we take into account that approximately 60–70% of therapeutic outcomes depend upon pharmacogenomic criteria (e.g., pathogenic mechanisms associated with AD-related genes), it can be postulated that pharmacogenetic and pharmacogenomic factors are responsible for 75–85% of the therapeutic response (efficacy) in AD patients treated with conventional drugs [4,24,25,36–38]. Of particular interest are the potential interactions of cholinesterase inhibitors with other drugs of current use in patients with AD, such as antidepressants, neuroleptics, antiarrhythmics, analgesics, and antiemetics, which are metabolized by the cytochrome P450 *CYP2D6* enzyme. Although most studies predict the safety of donepezil and galantamine, as the two principal cholinesterase inhibitors metabolized by CYP2D6-related enzymes few pharmacogenetic studies have been performed so far on an individual basis to personalize the treatment, and most studies reporting safety issues are the result of pooling together pharmacological and clinical information obtained with routine procedures. In certain cases, genetic polymorphism in the expression of *CYP2D6* is not expected to affect the pharmacodynamics of some cholinesterase inhibitors because major metabolic pathways are glucuronidation, O-demethylation, N-demethylation, N-oxidation, and epimerization. However, excretion rates are substantially different in EMs and PMs. For instance, in EMs, urinary metabolites resulting from O-demethylation of galantamine represent 33.2% of the dose compared with 5.2% in PMs, which show correspondingly higher urinary excretion of unchanged galantamine and its N-oxide [59]. Therefore, there are still many unanswered questions regarding the metabolism of cholinesterase inhibitors and their interaction with other drugs (potentially leading to ADRs) which require pharmacogenetic elucidation. It is also worth mentioning that dose titration (a common practice in AD patients treated with cholinesterase inhibitors, e.g., tacrine, donepezil) is an unwise strategy, since approximately 30–60% of drug failure or lack of therapeutic efficacy (and/or ADR manifestation) is not a matter of drug dosage but a problem of poor metabolizing capacity in PMs. As a general rule, it is recommended to avoid AChEIs (donepezil, galantamine) and major psychotropic drugs (neuroleptics, antidepressants) in *APOE-4/4* carriers and *CYP2D6*-PMs. In these particular cases (> 15%), alternative treatments should be administered.

To achieve a mature discipline of pharmacogenetics and pharmacogenomics in CNS disorders and dementia it would be convenient to accelerate the following processes: (a) to educate physicians and the public on the use of genetic/genomic screening in the daily clinical practice; (b) to standardize genetic testing for major categories of drugs; (c) to validate pharmacogenetic and pharmacogenomic procedures according to drug category and pathology; (d) to regulate ethical, social, and economic issues; and (e) to incorporate pharmacogenetic and pharmacogenomic procedures to both drugs in development and drugs on the market in order to optimize therapeutics [4,22–31,37–39,41].

Comprehensive genomic characterization defines human glioblastoma genes and core pathways

The Cancer Genome Atlas Research Network*

Human cancer cells typically harbour multiple chromosomal aberrations, nucleotide substitutions and epigenetic modifications that drive malignant transformation. The Cancer Genome Atlas (TCGA) pilot project aims to assess the value of large-scale multi-dimensional analysis of these molecular characteristics in human cancer and to provide the data rapidly to the research community. Here we report the interim integrative analysis of DNA copy number, gene expression and DNA methylation aberrations in 206 glioblastomas—the most common type of primary adult brain cancer—and nucleotide sequence aberrations in 91 of the 206 glioblastomas. This analysis provides new insights into the roles of *ERBB2*, *NF1* and *TP53*, uncovers frequent mutations of the phosphatidylinositol-3-OH kinase regulatory subunit gene *PIK3R1*, and provides a network view of the pathways altered in the development of glioblastoma. Furthermore, integration of mutation, DNA methylation and clinical treatment data reveals a link between *MGMT* promoter methylation and a hypermutator phenotype consequent to mismatch repair deficiency in treated glioblastomas, an observation with potential clinical implications. Together, these findings establish the feasibility and power of TCGA, demonstrating that it can rapidly expand knowledge of the molecular basis of cancer.

Cancer is a disease of genome alterations: DNA sequence changes, copy number aberrations, chromosomal rearrangements and modification in DNA methylation together drive the development and progression of human malignancies. With the complete sequencing of the human genome and continuing improvement of high-throughput genomic technologies, it is now feasible to contemplate comprehensive surveys of human cancer genomes. The Cancer Genome Atlas aims to catalogue and discover major cancer-causing genome alterations in large cohorts of human tumours through integrated multi-dimensional analyses.

The first cancer studied by TCGA is glioblastoma (World Health Organization grade IV), the most common primary brain tumour in adults[1]. Primary glioblastoma, which comprises more than 90% of biopsied or resected cases, arises *de novo* without antecedent history of low-grade disease, whereas secondary glioblastoma progresses from previously diagnosed low-grade gliomas[1]. Patients with newly diagnosed glioblastoma have a median survival of approximately 1 year with generally poor responses to all therapeutic modalities[2]. Two decades of molecular studies have identified important genetic events in human glioblastomas, including the following: (1) dysregulation of growth factor signalling via amplification and mutational activation of receptor tyrosine kinase (RTK) genes; (2) activation of the phosphatidylinositol-3-OH kinase (PI(3)K) pathway; and (3) inactivation of the p53 and retinoblastoma tumour suppressor pathways[1]. Recent genome-wide profiling studies have also shown remarkable genomic heterogeneity among glioblastoma and the existence of molecular subclasses within glioblastoma that may, when fully defined, allow stratification of treatment[3–8]. Albeit fragmentary, such baseline knowledge of glioblastoma genetics sets the stage to explore whether novel insights can be gained from a more systematic examination of the glioblastoma genome.

Results

Data release. As a public resource, all TCGA data are deposited at the Data Coordinating Center (DCC) for public access (http://cancergenome.nih.gov/). TCGA data are classified by data type (for example, clinical, mutations, gene expression) and data level to allow structured access to this resource with appropriate patient privacy protection. An overview of the data organization is provided in the Supplementary Methods, and a detailed description is available in the TCGA Data Primer (http://tcga-data.nci.nih.gov/docs/TCGA_Data_Primer.pdf).

Biospecimen collection

Retrospective biospecimen repositories were screened for newly diagnosed glioblastoma based on surgical pathology reports and clinical records (Supplementary Fig. 1). Samples were further selected for having matched normal tissues as well as associated demographic, clinical and pathological data (Supplementary Table 1). Corresponding frozen tissues were reviewed at the Biospecimen Core Resource (BCR) to ensure a minimum of 80% tumour nuclei and a maximum of 50% necrosis (Supplementary Fig. 1). DNA and RNA extracted from qualified biospecimens were subjected to additional quality control measurements (Supplementary Methods) before distribution to TCGA centres for analyses (Supplementary Fig. 2).

After exclusion based on insufficient tumour content ($n = 234$) and suboptimal nucleic acid quality or quantity ($n = 147$), 206 of the 587 biospecimens screened (35%) were qualified for copy number, expression and DNA methylation analyses. Of these, 143 cases had matched normal peripheral blood or normal tissue DNAs and were therefore appropriate for re-sequencing. This cohort also included 21 post-treatment glioblastoma cases used for exploratory comparisons

---

*Lists of participants and their affiliations appear at the end of the paper.

(Supplementary Table 1). Although it is possible that a small number of progressive secondary glioblastomas were among the remaining 185 cases of newly diagnosed glioblastomas, this cohort represents predominantly primary glioblastoma. Indeed, when compared with published cohorts, overall survival of the newly diagnosed glioblastoma cases in TCGA is similar to that of primary glioblastomas reported in the literature (Supplementary Fig. 3, $P = 0.2$)[9–12].

Genomic and transcriptional aberrations

Genomic copy number alterations (CNAs) were measured on three microarray platforms (Supplementary Methods) and analysed with multiple analytical algorithms[13–15] (Supplementary Fig. 4 and Supplementary Tables 2–4). In addition to the well-known alterations[3,13,14], we detected significantly recurrent focal alterations not previously reported in glioblastomas, such as homozygous deletions involving *NF1* and *PARK2*, and amplifications of *AKT3* (Fig. 1a and Supplementary Tables 2–4). Search for informative but infrequent CNAs also uncovered rare focal events, such as amplifications of *FGFR2* and *IRS2*, and deletion of *PTPRD* (Supplementary Table 4). Abundance of protein-coding genes and non-coding microRNA was also measured by transcript-specific and exon-specific probes on multiple platforms (Supplementary Methods). The resulting integrated gene expression data set showed that ~76% of genes within recurrent CNAs have expression patterns that correlate with copy number (Supplementary Table 2). In addition, single-nucleotide-polymorphism (SNP)-based analyses also catalogued copy-neutral loss of heterozygosity (LOH), with the most significant region being 17p, which contains *TP53* (Supplementary Methods).

Patterns of somatic nucleotide alterations in glioblastoma

A total of 91 matched tumour–normal pairs (72 untreated and 19 treated cases) were selected from the 143 cases for detection of somatic mutations in 601 selected genes (Supplementary Table 5). The resulting sequences, totalling 97 million base pairs (1.1 ± 0.1 million bases per sample), uncovered 453 validated non-silent somatic mutations in 223 unique genes, 79 of which contained two or more events (Supplementary Table 6; see also http://tcga-data.nci.nih.gov/docs/somatic_mutations/tcga_mutations.htm). The background mutation rates differed markedly between untreated and treated glioblastomas, averaging 1.4 versus 5.8 somatic silent mutations per sample (98 events among 72 untreated cases versus 111 among 19 treated, $P < 10^{-21}$), respectively. This difference was predominantly driven by seven hypermutated samples, as determined by frequencies of both silent and non-silent mutations (Fig. 1b, c). Four of the seven hypermutated tumours were from patients previously treated with temozolomide and three were from patients treated with CCNU (lomustine) alone or in combination (Supplementary Table 1b). A hypermutator phenotype in glioblastoma has been described in three glioblastoma specimens with *MSH6* mutations[16,17], prompting us to perform a systematic analysis of the genes involved in mismatch repair (MMR). Indeed, six of the seven hypermutated samples harboured mutations in at least one of the MMR genes *MLH1*, *MSH2*, *MSH6* or *PMS2*, as compared with only one sample among the eighty-four non-hypermutated samples ($P = 7 \times 10^{-8}$), suggesting a role of decreased DNA repair competency in these highly mutated samples derived from treated patients.

By applying a statistical analysis of mutation significance[18], we identified eight genes as significantly mutated (false discovery rate $<10^{-3}$) (Fig. 2d and Supplementary Table 6). Interestingly, 27 *TP53* mutations were detected in the 72 untreated glioblastomas (37.5%) and 11 mutations in the 19 treated samples (58%). All of those mutations clustered in the DNA binding domain, a well-known hotspot for p53 mutations in human cancers (Supplementary Fig. 5 and Supplementary Table 6). Given the predominance of primary

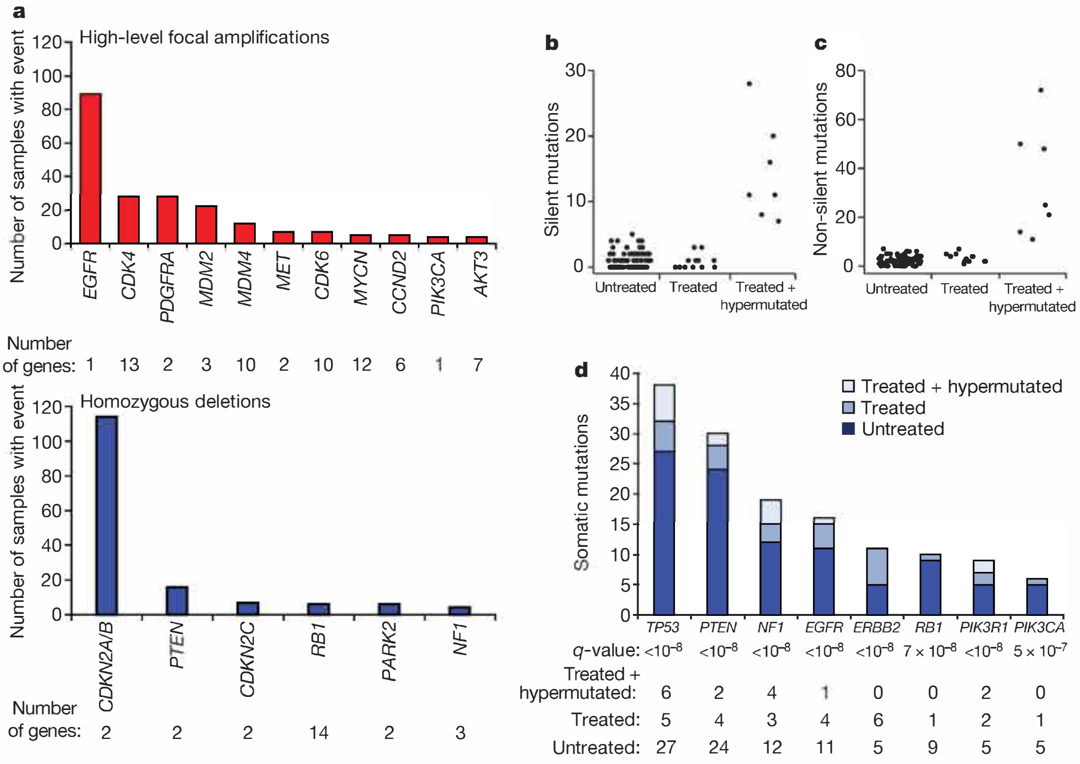

Figure 1 | Significant copy number aberrations and pattern of somatic mutations. **a**, Frequency and significance of focal high-level CNAs. Known and putative target genes are listed for each significant CNA, with 'Number of genes' denoting the total number of genes within each focal CNA boundary. **b, c**, Distribution of the number of silent (**b**) and non-silent (**c**) mutations across the 91 glioblastoma samples separated according to their treatment status, showing hypermutation in 7 out of the 19 treated samples. **d**, Significantly mutated genes in 91 glioblastomas. The eight genes attaining a false discovery rate <0.1 are displayed here. Somatic mutations occurring in untreated samples are in dark blue; those found in statistically non-hypermutated and hypermutated samples among the treated cohort are in respectively lighter shades of blue. Numbers of events in each group are noted.

glioblastoma among this newly diagnosed collection, that result unequivocally proves that p53 mutation is a common event in primary glioblastoma.

NF1 is a human glioblastoma suppressor gene. Although somatic mutations in *NF1* have been reported in a small series of human glioblastoma tumours[19], their role remains controversial[20], despite strong genetic data in mouse model systems[20–22]. Here, 19 *NF1* somatic mutations were identified in 13 samples (14% of 91), including 6 nonsense mutations, 4 splice site mutations, 5 missense changes and 4 frameshift insertions/deletions (indels) (Fig. 2a). Five of these mutations—R1391S (ref. 23), R1513* (ref. 24), e25 −1 and e29 +1 (ref. 25) and Q1966* (ref. 26)—have been reported as germline alterations in neurofibromatosis patients, and thus are probably inactivating. In addition, 30 heterozygous deletions in *NF1* were observed among the entire interim sample set of 206 cases, 6 of which also harbour point mutation (Supplementary Tables 8 and 9). Some samples also exhibited loss of expression without evidence of genomic alteration (Fig. 2b). Overall, at least 47 of these 206 patient samples (23%) harboured somatic *NF1* inactivating mutations or deletions, definitively addressing *NF1*'s relevance to sporadic human glioblastoma.

Prevalence of *EGFR* family activation. EGFR is frequently activated in primary glioblastomas. Variant III deletion of the extracellular domain ('vIII mutant')[27] has been the most commonly described event, in addition to extracellular domain point mutations and cytoplasmic domain deletions[28,29]. Here, high-resolution genomic and exon-specific transcriptomic profiling readily detected vIII and carboxy-terminal deletions with correspondingly altered transcripts (Fig. 2c). Among the 91 glioblastoma cases with somatic mutation data, 22 harboured focal amplification of wild-type *EGFR* with no point mutation, 16 had point mutations in addition to focal amplification, and 3 had *EGFR* point mutations but no amplification (Supplementary Fig. 6 and Supplementary Table 9). Collectively, *EGFR* alterations were observed in 41 of the 91 sequenced samples.

ERBB2 mutation has previously been reported in only one glioblastoma tumour[30]. In the TCGA cohort, 11 somatic *ERBB2* mutations in 7 of 91 samples were validated, including 3 in the kinase domain and 2 involving V777A, a site of recurrent missense and in-frame insertion mutations in lung, gastric and colon cancers[31]. The remaining eight mutations (including seven missense and one splice-site mutation) occurred in the extracellular domain of the protein, similar to somatic *EGFR* substitutions in glioblastoma (Fig. 2d). Unlike in breast cancers, focal amplifications of *ERBB2* were not observed in glioblastomas.

Somatic mutations of the PI(3)K complex in human glioblastoma. The PI(3)K complex consists of a catalytically active protein, p110α, encoded by *PIK3CA*, and a regulatory protein, p85α, encoded by *PIK3R1*. Frequent activating missense mutations of *PIK3CA* have been reported in multiple tumour types, including glioblastoma[32,33]. These mutations occur primarily in the adaptor binding domain (ABD) as well as the C2 helical and kinase domains[34–36]. Indeed, *PIK3CA* somatic nucleotide substitutions were detected in 6 of the 91 sequenced samples (Supplementary Table 6). Apart from the four mutations already reported in the COSMIC database (http://www.sanger.ac.uk/genetics/CGP/cosmic/), two novel in-frame deletions were detected in the adaptor binding domain of *PIK3CA* ('L10del' and 'P17del'). Those deletions may disrupt interactions between p110α and its regulatory subunit, p85α (ref. 37).

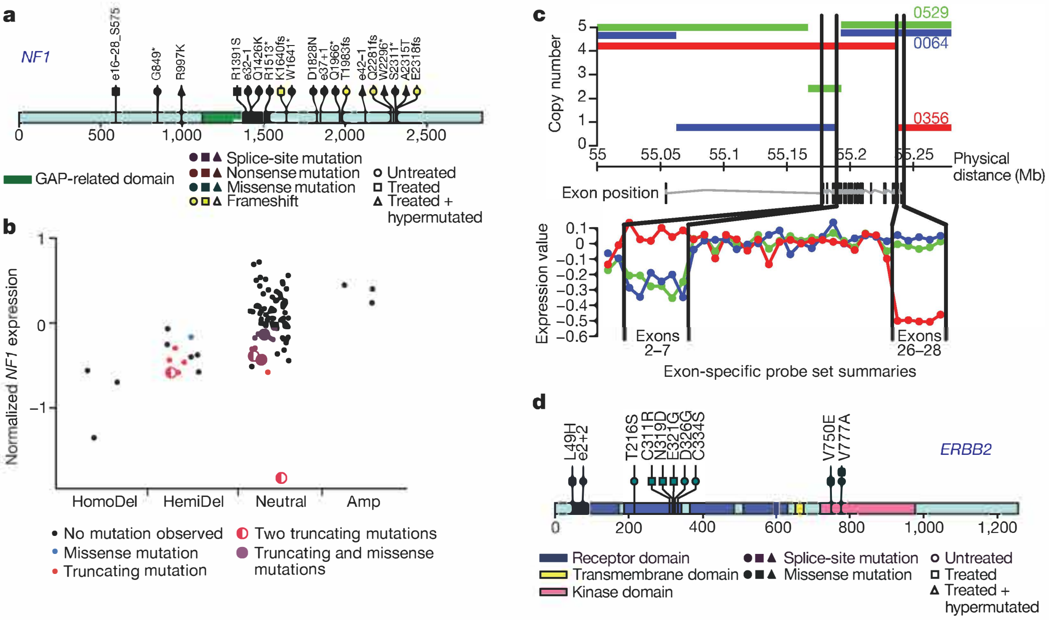

Figure 2 | Mutations in *NF1* tumour suppressor gene and *EGFR* family members. **a**, *NF1* somatic mutations in 91 glioblastoma tumours. Both missense mutations and truncating nonsense, frameshift and splice site mutations were observed. Splice positions are given in number of bases to the closest exon (e#) numbered according to the *NF1* reference transcript in the Human Gene Mutation Database; positive indicates 3′ of exon, negative indicates 5′ of exon. Asterisk indicates a stop codon. fs, frameshift. **b**, Correlation of copy number and mutation status at the *NF1* locus with level of expression (*y* axis). Mutation events predicted to result in fewer expressed copies (including deletion, nonsense, splice site and frameshift mutations) generally have lower observed expression. HomoDel, homozygous deletion; HemiDel, single-copy loss; Neutral, no change in copy number (presumed diploid); Amp, increased copy number. Copy number status of the *NF1* locus in each sample was determined as described in the Supplementary Information. **c**, DNA copy number and mRNA expression profiles for TCGA samples TCGA-08-0356 (red), TCGA-02-0064 (blue) and TCGA-02-0529 (green) at the *EGFR* locus. The upper panel shows the segmented DNA copy number (based on Affymetrix SNP6.0 data) versus genomic coordinates on chromosome 7. The lower panel shows relative exon expression levels across the known *EGFR* exons from the Affymetrix Exon array ordered by genomic position, where relative expression is the median-centred difference in exon intensity and gene intensity. The *EGFR* gene model lies between the two plots. Black lines map the genomic positions of exons 2 through to 7 and 26 through to 28. Note that structural deletions cause the relatively lower expression of exons 2–7 in the green and blue samples and exons 26–28 in the red sample. **d**, *ERBB2* somatic mutations in 91 glioblastoma tumours. Mutations cluster in the extracellular domain as seen in *EGFR* in glioblastoma. Splice site mutation position is given in number of bases to the closest exon (e#); positive indicates 3′ of exon.

Unlike *PIK3CA*, *PIK3R1* has rarely been reported as mutated in cancers. Among the five reported *PIK3R1* nucleotide substitutions in cancers[38,39], one was in a glioblastoma[39]. In our TCGA cohort, 9 *PIK3R1* somatic mutations were detected among the 91 sequenced glioblastomas. None of them was in samples with *PIK3CA* mutations. Of the nine mutations, eight lay within the intervening SH2 (or iSH2) domain and four are 3-bp in-frame deletions (Fig. 3a and Supplementary Table 6). In accord with the crystal structure of PI(3)K, which identifies the D560 and N564 amino acid residues in p85α as contact points with the N345 amino acid residue in the C2 domain of p110α (ref. 37), the mutations detected in glioblastoma cluster around those three amino acid residues (Fig. 3b), including a N345K mutation in *PIK3CA* (previously reported in colon and breast cancers[40]) and D560Y and N564K mutations in *PIK3R1*. We also identified an 18-bp deletion spanning residues D560 to S565 (DKRMNS) in *PIK3R1* (Fig. 3b) in addition to three other novel deletions (R574del, T576del and W583del) in proximity to the two key residues. We speculate that spatial constraints due to these deletions might prevent inhibitory contact of the p85α N-terminal SH2 (nSH2) domain with the helical domain of p110α, causing constitutive PI(3)K activity. Taken together, the pattern of clustering of the mutations around key residues defined by the crystal structure of PI(3)K strongly suggests that these novel *PIK3R1* point mutations and indels disrupt the important C2–iSH2 interaction, relieving the inhibitory effect of p85α on p110α.

Figure 3 | *PIK3R1* and *PIK3CA* mutations in glioblastoma. **a**, The locations of mutations found in TCGA tumours are indicated above the backbone. ABD, adaptor binding domain; RBD, Ras binding domain; C2, membrane-binding domain; nSH2, N-terminal SH2 domain; iSH2, inter-SH2 domain; cSH2, C-terminal SH2 domain. **b**, Three mutations found in the interaction interface of the C2 domain of p110α with iSH2 of p85α. Two residues of p85α, D560 and N564, are within hydrogen-bonding distance of the C2 residue of p110α, N345.

MGMT methylation and MMR in treated glioblastomas

Cancer-specific DNA methylation of CpG dinucleotides located in CpG islands within the promoters of 2,305 genes was measured relative to normal brain DNA (Supplementary Table 7 and Supplementary Methods). The promoter methylation status of *MGMT*, a DNA repair enzyme that removes alkyl groups from guanine residues[41], is associated with glioblastoma sensitivity to alkylating agents[42,43]. Among the 91 sequenced cases, 19 samples were found to contain *MGMT* promoter methylation (including 13 of the 72 untreated cases and 6 of the 19 treated cases). When juxtaposed with somatic mutation data, an

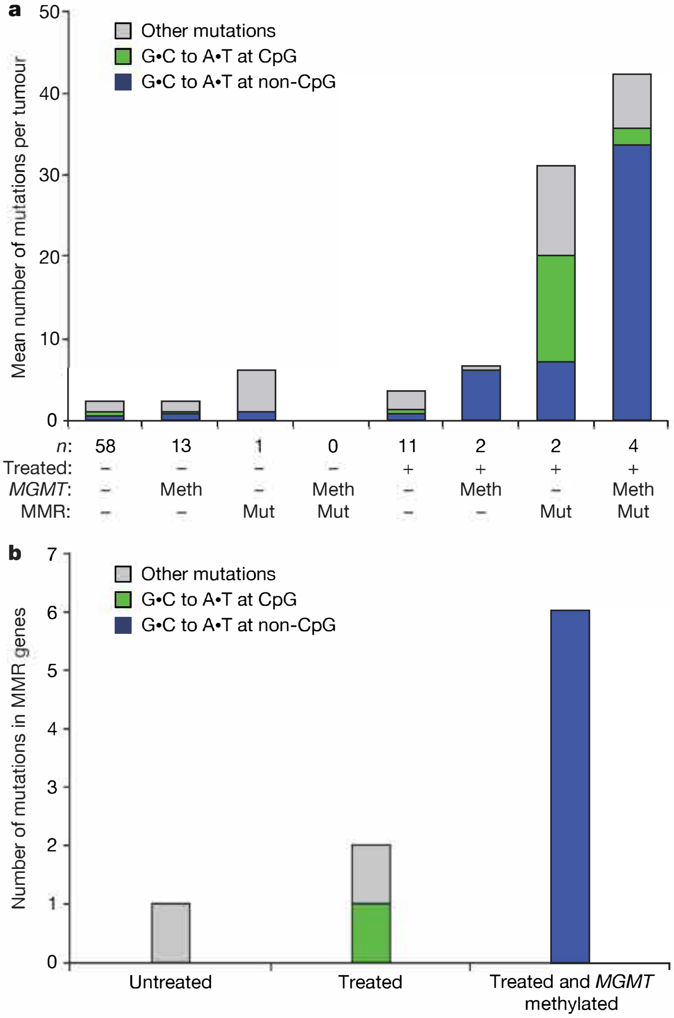

Figure 4 | Pattern of somatic mutations, *MGMT* DNA methylation and MMR gene mutations in treated glioblastomas. **a**, The mean number of validated somatic nucleotide substitutions per tumour for key sample groups is indicated on the *y* axis and denoted by the height of the bar histograms. Samples are grouped along the *x* axis according to treatment status of the patient (minus indicates untreated; plus indicates treated), DNA methylation status of *MGMT* (Meth, DNA methylated; minus, not methylated), and genetic status of MMR genes (minus, no genes mutated; Mut, one or more of the *MLH1*, *MSH2*, *MSH6* or *PMS2* genes mutated); the number below each bar indicates the number of samples in the group. Bars are colour-coded for types of nucleotide substitutions including G-to-A transitions at non-CpG sites (blue), G-to-A transitions at CpG sites (green), and other mutation types (grey). **b**, Bar histogram for mutation spectrum in the MMR genes as a function of treatment status and methylation status of *MGMT*. The colour code for substitution types is the same as in **a**.

intriguing relationship between the hypermutator phenotype and *MGMT* methylation status emerged in the treated samples. Specifically, *MGMT* methylation was associated with a profound shift in the nucleotide substitution spectrum of treated glioblastomas (Fig. 4a). Among the 13 treated samples without *MGMT* methylation, 29% (29 out of 99) of the validated somatic mutations occurred as G•C to A•T transitions in CpG dinucleotides (characteristic of spontaneous deamination of methylated cytosines), and a comparable 23% (23 out of 99) of all mutations occurred as G•C to A•T transitions in non-CpG dinucleotides. In contrast, in the six treated samples with *MGMT* methylation, 81% of all mutations (146 out of 181) turned out to be of the G•C to A•T transition type in non-CpG dinucleotides, whereas only 4% (8 out of 181) of all mutations were G•C to A•T transition mutations within CpGs. That pattern is consistent with a failure to repair alkylated guanine residues caused by treatment. In other words, *MGMT* methylation shifted the mutation spectrum of treated samples to a preponderance of G•C to A•T transition at non-CpG sites.

Notably, the mutational spectra in the MMR genes themselves reflected *MGMT* methylation status and treatment consequences. All seven mutations in MMR genes found in six *MGMT* methylated, hypermutated (treated) tumours occurred as G•C to A•T mutations at non-CpG sites (Fig. 4b and Supplementary Table 6), whereas neither MMR mutation in non-methylated, hypermutated tumours was of this characteristic. Hence, these data show that MMR deficiency and *MGMT* methylation together, in the context of treatment, exert a powerful influence on the overall frequency and pattern of somatic point mutations in glioblastoma tumours, an observation of potential clinical importance.

Integrative analyses define glioblastoma core pathways

To begin to construct an integrated view of common genetic alterations in the glioblastoma genome, we mapped the unequivocal genetic alterations—validated somatic nucleotide substitutions, homozygous deletions and focal amplifications—onto major pathways implicated in glioblastoma[1]. That analysis identified a highly interconnected network of aberrations (Supplementary Figs 7 and 8), including three major pathways: RTK signalling, and the p53 and RB tumour suppressor pathways (Fig. 5).

By copy number data alone, 66%, 70% and 59% of the 206 samples harboured somatic alterations in core components of the RB, TP53 and RTK pathways, respectively (Supplementary Table 8). In the 91 samples for which there was also sequencing data, the frequencies of somatic alterations increased to 87%, 78% and 88%, respectively (Supplementary Table 9). There was a statistical tendency towards mutual exclusivity of alterations of components within each pathway (*P*-values of 9.3×10^{-10}, 2.5×10^{-13} and 0.022, respectively, for the p53, RB and RTK pathways; Supplementary Table 10), consistent with the thesis that deregulation of one component in the pathway relieves the selective pressure for additional ones. However, we observed a greater than random chance (one-tailed, $P = 0.0018$) that a given sample harbours at least one aberrant gene from each of the three pathways (Supplementary Table 10). In fact, 74% harboured aberrations in all three pathways, a pattern suggesting that deregulation of the three pathways is a core requirement for glioblastoma pathogenesis.

As well as frequent deletions and mutations of the *PTEN* lipid phosphatase tumour suppressor gene, 86% of the glioblastoma samples harboured at least one genetic event in the core RTK/PI3K pathway (Fig. 5a). In addition to *EGFR* and *ERBB2*, *PDGFRA* (13%) and *MET* (4%) showed frequent aberrations (Supplementary Table 9). A total of 10 of the 91 sequenced samples have amplifications or point mutations in at least 2 of the 4 RTKs catalogued (*EGFR*, *ERBB2*, *PDGFRA* and *MET*; Supplementary Table 9), suggesting that genomic activation can be a mechanism for co-activated RTKs[44].

Figure 5 | Frequent genetic alterations in three critical signalling pathways. **a**–**c**, Primary sequence alterations and significant copy number changes for components of the RTK/RAS/PI(3)K (**a**), p53 (**b**) and RB (**c**) signalling pathways are shown. Red indicates activating genetic alterations, with frequently altered genes showing deeper shades of red. Conversely, blue indicates inactivating alterations, with darker shades corresponding to a higher percentage of alteration. For each altered component of a particular pathway, the nature of the alteration and the percentage of tumours affected are indicated. Boxes contain the final percentages of glioblastomas with alterations in at least one known component gene of the designated pathway.

Inactivation of the p53 pathway occurred in the form of *ARF* deletions (55%), amplifications of *MDM2* (11%) and *MDM4* (4%), in addition to mutations of p53 itself (Fig. 5b and Supplementary Table 8). Among 91 sequenced samples (Supplementary Table 9), genetic lesions in *TP53* were mutually exclusive of those in *MDM2* or *MDM4* (odds ratios of 0.00 for both; $P = 0.02$ and 0.068, respectively; Supplementary Table 10), but not of those in *ARF*. In fact, 10 of the 32 tumours with *TP53* mutations also had deleted *ARF*, suggesting that homozygous deletion of the *CDKN2A* locus (which encodes both $\mathrm{p16}^{\mathrm{INK4A}}$ and ARF) was at least in part driven by $\mathrm{p16}^{\mathrm{INK4A}}$.

Among the 77% samples harbouring RB pathway aberrations (Fig. 5c), the most common event was deletion of the *CDKN2A*/*CDKN2B* locus on chromosome 9p21 (55% and 53%), followed by amplification of the *CDK4* locus (14%) (Fig. 5c and Supplementary Tables 8 and 9). Although CNAs in the CDK/RB pathway members can co-occur in the same tumour[14], all nine samples with *RB1* nucleotide substitutions (Supplementary Table 9) lacked *CDKN2A*/*CDKN2B* deletion or other CNAs in the pathway, suggesting that inactivation of *RB1* by nucleotide substitution, in contrast to copy number loss, obviates the genetic pressure for activation of upstream cyclin/cyclin-dependent kinases.

Discussion

In establishing this pilot programme, TCGA has developed important principles in biospecimen banking and collection, and established the infrastructure that will serve similar efforts in the future. Although it ensured high-quality data, the stringent biospecimen selection criteria may have introduced a degree of bias because small samples and samples with high levels of necrosis were excluded. Nonetheless, the clinical parameters of this cohort are similar to other published cohorts (Supplementary Fig. 3 and Supplementary Table 1).

The integrated analyses of multi-dimensional genomic data from complementary technology platforms have proved informative. In addition to pinpointing deregulation of RB, p53 and RTK/RAS/PI(3)K pathways as obligatory events in most, and perhaps all, glioblastoma tumours, the patterns of mutations may also inform future therapeutic decisions. It would be reasonable to speculate that patients with deletions or inactivating mutations in *CDKN2A* or *CDKN2C* or patients with amplifications of *CDK4*/*CDK6* would be candidates for treatment with CDK inhibitors, a strategy not likely to be effective in patients with *RB1* mutation. Similarly, patients with *PTEN* deletions or activating mutations in *PIK3CA* or *PIK3R1* might be expected to benefit from a PI(3)K or PDK1 inhibitor, whereas tumours in which the PI(3)K pathway is altered by *AKT3* amplification might prove refractory to those modalities. The presence of genomic co-amplification reinforces the recent report of multiple phosphorylated (activated) RTKs in individual glioblastoma specimens[44], suggesting a way to tailor anti-RTK therapeutic cocktails to specific patterns of RTK mutation. In addition, combination anti-RTK therapy might synergize with downstream inhibition of PI(3)K or cell cycle mediators. In contrast, glioblastomas with *NF1* mutations might benefit from a RAF or MEK inhibitor as part of a combination, as shown for *BRAF* mutant cancers[45].

One of the most important biomarkers for glioblastomas is the methylation status of *MGMT*, which predicts sensitivity to temozolomide[42,43], an alkylating agent that is the current standard of care for glioblastoma patients. Integrative analysis of mutation, DNA methylation and clinical (treatment) data, albeit with small sample numbers, suggests a series of inter-related events that may have an impact on clinical response and outcome. Newly diagnosed glioblastomas with *MGMT* methylation respond well to treatment with alkylating agents, in part as a consequence of unrepaired alkylated guanine residues initiating cycles of futile mismatch repair, which can lead to cell death[46–48]. Therefore, treatment of *MGMT*-deficient glioblastomas with alkylating therapy introduces a strong selective pressure to lose mismatch repair function[49]. That conclusion is consistent with our observation that the mismatch repair genes themselves are mutated with characteristic C•G to A•T transitions at non-CpG sites resulting from unrepaired alkylated guanine residues. Thus, initial methylation of *MGMT*, in conjunction with treatment, may lead to both a shift in mutation spectrum affecting mutations at mismatch repair genes and selective pressure to lose mismatch repair function. In other words, our finding raises the possibility that patients who initially respond to the frontline therapy in use today may evolve not only treatment resistance, but also an MMR-defective hypermutator phenotype. If such a hypothesis is validated, one may speculate that selective strategies designed to target mismatch-repair-deficient cells[50] would represent a rational upfront combination with alkylating agent that together may prevent or minimize emergence of such resistance. Conversely, such a treatment-mediated mutator phenotype may enhance pathway mutations that can confer resistance to targeted therapies, thereby cautioning the combination of alkylating agents with targeted agents, as this may substantially increase the probability of developing resistance to such targeted drugs.

The power of TCGA to produce unprecedented multi-dimensional data sets using statistically robust numbers of samples sets the stage for a new era in the discovery of new cancer interventions. The integrative analyses leading to the formulation of an unanticipated hypothesis on a potential mechanism of resistance highlights precisely the value and power of such project design, demonstrating how unbiased and systematic cancer genome analyses of large sample cohorts can lead to important discoveries.

METHODS SUMMARY

Biospecimens were screened from retrospective banks of tissue source sites under appropriate Institutional Review Board approvals for newly diagnosed glioblastoma with minimal 80% tumour cell percentage. RNA and DNA extracted from qualified specimens were distributed to TCGA centres for analysis. Whole-genome-amplified genomic DNA samples from tumours and normal samples were sequenced by the Sanger method. Mutations were called, verified using a second genotyping platform, and systematically analysed to identify significantly mutated genes after correcting for the background mutation rate for nucleotide type and the sequence coverage of each gene. DNA copy number analyses were performed using the Agilent 244K, Affymetrix SNP6.0 and Illumina 550K DNA copy number platforms. Sample-specific and recurrent copy number changes were identified using various algorithms (GISTIC, GTS, RAE). Messenger RNA and microRNA (miRNA) expression profiles were generated using Affymetrix U133A, AffymetrixExon 1.0 ST, custom Agilent 244K, and Agilent miRNA array platforms. mRNA expression profiles were integrated into a single estimate of relative gene expression for each gene in each sample. Methylation at CpG dinucleotides was measured using the Illumina GoldenGate assay. All data for DNA sequence alterations, copy number, mRNA expression, miRNA expression and CpG methylation were deposited in standard common formats in the TCGA DCC at http://cancergenome.nih.gov/dataportal/. All archives submitted to DCC were validated to ensure a common document structure and to ensure proper use of identifying information.

Acknowledgements We thank the members of TCGA's External Scientific Committee, the Glioblastoma Disease Working Group (http://cancergenome.nih.gov/components) and D. N. Louis for discussions; A. Mirick, J. Melone and C. Collins for administrative coordination of TCGA activities; and L. Gaffney for graphic art. This work was supported by the following grants from the United States National Institutes of Health: U54HG003067, U54HG003079, U54HG003273, U24CA126543, U24CA126544, U24CA126546, U24CA126551, U24CA126554, U24CA126561 and U24CA126563.

Author Contributions The TCGA research network contributed collectively to this study. Biospecimens were provided by the tissue source sites and processed by the Biospecimen Core Resource. Data generation and analyses were performed by the genome sequencing centres and cancer genome characterization centres. All data were released through the Data Coordinating Center. Project activities were coordinated by the NCI and NHGRI project teams. The following TCGA investigators contributed substantively to the writing of this manuscript. **Leaders:** L. Chin and M. Meyerson. **Neuropathology:** K. Aldape, D. Bigner, T. Mikkelsen and S. VandenBerg. **Databases:** A. Kahn. **Biospecimen analysis:** R. Penny, M. L. Ferguson and D. S. Gerhard. **Copy number:** G. Getz, C. Brennan, B. S. Taylor, W. Winckler, P. Park and M. Ladanyi. **Gene expression:** K. A. Hoadley, R. G. W. Verhaak, D. N. Hayes and P. Spellman. **LOH:** D. Absher and B. A. The Application of Genomics in Diabetes: Barriers to Discovery and Implementation

James S. Floyd[1] and Bruce M. Psaty[1,2,3]

Diabetes Care 2016;39:1858–1869 | DOI: 10.2337/dc16-0738

The emerging availability of genomic and electronic health data in large populations is a powerful tool for research that has drawn interest in bringing precision medicine to diabetes. In this article, we discuss the potential application of genomics to the prediction, prevention, and treatment of diabetes, and we use examples from other areas of medicine to illustrate some of the challenges involved in conducting genomics research in human populations and implementing findings in practice. At this time, a major barrier to the application of genomics in diabetes care is the lack of actionable genomic findings. Whether genomic information should be used in clinical practice requires a framework for evaluating the validity and clinical utility of this approach, an improved integration of genomic data into electronic health records, and the clinical decision support and educational resources for clinicians to use these data. Efforts to identify optimal approaches in all of these domains are in progress and may help to bring diabetes into the era of genomic medicine.

Many anticipated that the completion of the Human Genome Project over 10 years ago would mark the beginning of a new era of genomic medicine, in which new approaches to discovery research, disease prediction, and treatment would develop from an improved understanding of the genetic causes of human disease. In some areas of medicine, genomic discoveries have led to important new treatments. Genetic association studies have demonstrated that loss-of-function mutations in *PCSK9* result in low levels of LDL cholesterol and a reduced risk of coronary heart disease (1,2), This discovery led to a new class of drugs with dramatic lipid-lowering effects (3,4). In oncology, there has been a shift from using older drugs with broad cytotoxic effects to therapies that target specific mutations in driver genes (5), resulting in impressive reductions in mortality for some cancers (6).

Beyond the discovery of new drug targets, genomic information can be used to predict the occurrence of disease and to identify subgroups of patients for whom existing therapies or interventions will have the greatest efficacy or the least adverse effects. These are key elements of an approach that is now called precision medicine (7). Successes in oncology and other technological developments—the rapidly decreasing cost of whole-genome sequencing (8), improvements in informatics, and the widespread adoption of electronic health records (9–11)—have galvanized interest in applying various forms of big data, including genomics, to diseases such as diabetes (12). In this article, we discuss the application of genomics to diabetes, with a focus on some of the challenges involved in conducting genomics research in human populations and implementing findings in practice.

GENOMICS IN THE PREDICTION, PREVENTION, AND DIAGNOSIS OF DIABETES

The incidence and prevalence of diabetes have doubled over the past two decades (13), and there are now about 30 million adults in the U.S. living with this condition, 95% of whom have type 2 diabetes (14). Genome-wide association (GWA) studies test hundreds of thousands or even millions of common (minor allele frequency [MAF] >5%) and low-frequency (MAF 1–5%) variants across both protein coding (exonic) and noncoding (intronic) regions of the genome. Large GWA studies have identified more than 50 genetic loci associated with various glycemic traits and at least 90 loci associated with type 2 diabetes (15–18). These genetic variants, which may explain as much as 10% of the variance in disease susceptibility, have advanced our understanding of the biology of diabetes, but each genetic locus confers only a small increase in risk. For example, the common variant from these GWA studies most strongly associated with type 2 diabetes, an intronic variant in *TCF7L2* (rs7903146), is associated with a 37% increased relative risk per copy of the variant allele (19). Rare variants (MAF <1%) and variants that are common only in specific ancestral populations have been associated with a greater increase in diabetes risk, but they account for less of the overall burden of diabetes (20–22).

Genetic risk scores (GRSs) that combine information from multiple genetic variants have been evaluated as a tool for the prediction of type 2 diabetes. Meigs et al. (23) found that a GRS with 18 variants was significantly associated with the risk of developing type 2 diabetes in the Framingham Heart Study (FHS) (odds ratio [OR] 1.12 per variant allele) and that persons in the highest out of three risk categories had an OR of 2.6 for developing type 2 diabetes compared with persons in the lowest risk category. However, this GRS did not improve the prediction of diabetes beyond traditional nongenetic risk factors (23), and the same was true for an updated GRS that included 65 variants (24). To put this into perspective, a prognostic marker with an OR of 3.0 that correctly identifies 80% of persons who will develop diabetes would incorrectly classify 60% of persons who will not develop diabetes (25); this degree of discrimination is not useful clinically (26).

Biologic pathways other than heritable changes in DNA sequence may also be important predictors of diabetes and account for some of the variability in diabetes susceptibility not explained by genetics or traditional environmental factors. For example, DNA methylation at CpG sites, a key epigenetic mechanism for the regulation of gene expression, has been associated with the risk of type 2 diabetes (27,28). Metabolomic profiles of amino acids and other small molecules may also play a role (29), particularly among younger adults (30). However, these new types of "omics" suffer from the traditional epidemiologic limitations of confounding and reverse causality and will require rigorous evaluation before their clinical validity and utility are understood.

Risk prediction tools are most useful when there are effective and safe prevention measures, which may include behavioral interventions or drug therapies. For high-risk adults, the Diabetes Prevention Program (DPP) lifestyle intervention reduces the risk of type 2 diabetes by more than half (31), and this intervention is now offered throughout the country at programs recognized by the Centers for Disease Control and Prevention. Although the highly effective DPP lifestyle intervention has few or no adverse effects, the identification of persons who benefit the most from the intervention could help to prioritize its deployment in resource-limited settings. Florez and colleagues (32,33) have evaluated whether several genetic variants associated with diabetes risk modified the effectiveness of the lifestyle intervention in the original DPP study, and they found little evidence of effect modification based on genetic risk. Some have argued that communicating genetic information on disease risk might help to motivate healthy behaviors, but current evidence does not support this claim (34). For example, in a small randomized controlled trial (RCT) of participants with type 2 diabetes who all underwent an intensive lifestyle intervention directed at weight loss, those who received information on their genetic risk for diabetes had the same self-reported motivation and adherence to the intervention as those who did not (35).

If genetic tests are not helpful in the prediction and prevention of diabetes, they could have a role in discriminating between type 1 and type 2 diabetes. The epidemic of obesity (36) has made it more difficult to distinguish diabetes type because many children and young adults with type 1 diabetes are also obese (37). Misclassification poses significant risks; an incorrect diagnosis of type 2 diabetes may lead to inappropriate treatment with oral glucose-lowering drugs, and an incorrect diagnosis of type 1 diabetes may lead to unnecessary insulin treatment. In a recent cross-sectional study of type 1 and type 2 diabetes, Oram et al. (38) evaluated a GRS that included high-risk HLA genotypes and 31 genetic loci for type 2 diabetes. They found that this GRS improved the discrimination between strictly defined type 1 and type 2 diabetes when added to clinical factors and autoimmune antibody tests, and it also helped to predict who would require insulin treatment within 3 years of diagnosis (38). One advantage of a diagnostic tool based on genotype is that, unlike islet cell antibodies, the result does not change over time. However, before this type of genetic testing can be recommended for routine use in the clinic, further evaluation in prospective studies will be necessary to demonstrate not only accurate discrimination between type 1 and type 2 diabetes but also improved use of appropriate glucose-lowering treatment.

Most cases of diabetes have multiple genetic and environmental causes and are classified according to the presumed pathophysiologic defect—autoimmune destruction of β-cells leading to insulin deficiency for type 1 diabetes and varying degrees of insulin resistance and deficiency for type 2 diabetes. In other words, the vast majority of diabetes is polygenic, and despite the growth in knowledge about the various genetic causes of diabetes in recent years, classification of individual cases into meaningful subtypes based on the underlying genetics has been difficult. On the other hand, genetic testing may be useful for the diagnosis of certain forms of diabetes caused by defects in a single gene, such as *HNF1A* mutations for maturity-onset diabetes of the young (MODY)

(39) and activating *KCNJ11* mutations for neonatal diabetes (40), both of which are highly responsive to sulfonylurea therapy. These monogenic forms of diabetes account for ~1–2% of diabetes cases (41,42), and they typically present at a young age (<25 years) and follow an autosomal dominant pattern of inheritance. Targeted genotyping could also play a role in the diagnosis of type 2 diabetes in specific populations. For example, a rare missense variant in *HNF1A* (p.E508K) that increased the risk of diabetes fivefold was present among 2% in a study of Latinos in the southern U.S. with type 2 diabetes (20); additional studies are needed to determine whether this functional variant shares the sulfonylurea-responsiveness of the *HNF1A* variants that cause MODY.

PHARMACOGENOMICS OF THERAPIES FOR TYPE 2 DIABETES

Although, among persons with diabetes, the rates of microvascular (retinopathy, neuropathy, kidney disease) and cardiovascular complications have decreased by about half over the past two decades, they still occur more often among persons with diabetes than among individuals without diabetes (43). Reducing these risks is the major goal of glucose-lowering therapy. For type 1 diabetes, the long-term benefits of intensive insulin therapy are well established (44,45). For type 2 diabetes, intensive glucose-lowering therapy prevents microvascular complications, and postrandomization follow-up data from several RCTs suggest there may be long-term cardiovascular benefits as well (46–48).

There are now several classes of medications approved for the treatment of diabetes (Table 1). Most oral therapies have similar average effects on hemoglobin A_{1c} (HbA_{1c}), but they differ in their contraindications and side effects (49,50). There is surprisingly little information about the comparative benefits and harms for different drugs (51), and treatment guidelines for type 2 diabetes (52) permit the use of most approved drug classes as second-line therapy after metformin, which is the recommended first-line therapy for most patients because of its good safety profile and potential cardiovascular benefits (53,54). There is also substantial interindividual variability in drug response (55), and many patients eventually fail to achieve recommended levels of glycemic control with their initial therapy (56,57). For example, in the U.K. General Practice Research Database, only half of patients who initiated therapy with metformin or a sulfonylurea achieved an HbA_{1c} level of <7% (58). The factors that account for this variation are not well understood (59). Because of the wide range of side effects from different therapies and because of the person-to-person variability in treatment response and adverse effects, pharmacogenomic testing for genetic variants that define subgroups of patients who are most likely to benefit from or least likely to be harmed by specific drugs is an attractive potential application of genomics in diabetes.

Pharmacogenomic studies have typically focused on candidate genes involved in pharmacokinetics (absorption, distribution, metabolism, and elimination) or pharmacodynamics (the biologic effect of a drug on its target) (60). The pharmacogenomics of oral diabetes therapies has been reviewed in detail elsewhere (61–63); selected findings for the most extensively studied drugs, sulfonylureas and metformin, are listed in Table 2. Sulfonylureas undergo metabolism by cytochrome P450 (CYP) enzyme 2C9, and loss-of-function variants in the *CYP2C9* gene have been associated with greater glucose-lowering effects and an increased risk of hypoglycemia (64,65). The genes encoding the sulfonylurea receptor, *KCNJ11* and *ABCC8*, have also been associated with increased sulfonylurea response in some studies (66,67) but not others (68,69), and in one study the association was in the opposite direction (70). Unlike sulfonylureas, metformin does not undergo metabolism by CYP enzymes; it is excreted intact by the kidneys (71). Genes encoding several transporters that facilitate the movement of metformin into the bloodstream, into target tissues, and into renal tubular cells have been associated with effects on serum levels of metformin, glucose-lowering effect, and drug intolerance (72,73).

Candidate gene studies of sulfonylureas and metformin have not typically accounted for false positives from multiple comparisons, and most findings from these studies have failed to replicate

Table 1—Classes of medications commonly used to treat diabetes

Drug classes	Oral	Average HbA_{1c} reduction	Other benefits	Adverse effects	Cost
Metformin	Yes	~1.0–1.5	Weight loss, possible cardiovascular benefit	Lactic acidosis (rare), gastrointestinal side effects	Low
Sulfonylureas	Yes	~1.0–1.5		Hypoglycemia, weight gain, potential cardiovascular risk	Low
Meglitinides	Yes	~1.0		Hypoglycemia, weight gain	Moderate
Thiazolidinediones	Yes	~1.0		Heart failure, myocardial infarction (rosiglitazone), bone loss and fractures	Moderate
α-Glucosidase inhibitors	Yes	~0.8		Flatulence, diarrhea	Moderate
Amylin analog	No	~0.6		Hypoglycemia, nausea	High
DPP-4 inhibitors	Yes	~0.6–0.8		Potential heart failure (saxagliptin)	High
GLP-1 receptor agonists	No	~1.0	Weight loss	Nausea, vomiting, diarrhea	High
SGLT2 inhibitors	Yes	~0.6–0.8	Possible cardiovascular benefit	Genitourinary infections, ketoacidosis (rare)	High
Insulin	No	Unlimited	Most potent treatment	Hypoglycemia, weight gain	Low-high

Adapted from refs. 49,50. DPP-4, dipeptidyl peptidase 4; GLP-1, glucagon-like peptide 1; SGLT2, sodium–glucose cotransporter 2.

Table 2—Selected pharmacogenomic findings for sulfonylureas and metformin

Drug	Locus	Phenotype	*N*	Effect**	Refs.
Sulfonylureas					
Pharmacokinetic	*CYP2C9*	HbA_{1c} response	1,073	0.5% absolute greater reduction in HbA_{1c} (homozygous for variant alleles)	64
		FBG response	475	No association	75
		Hypoglycemia	357	OR 5.2 for hypoglycemia (homozygous for variant alleles)	65
Pharmacodynamic	*KCNJ11/ABCC8**	HbA_{1c} and FBG response	1,268	3.5% relative greater reduction in HbA_{1c} and 7.7% relative greater reduction in FBG (homozygous for variant alleles)	66
		HbA_{1c} response	101	0.2% absolute greater reduction in HbA_{1c} (per variant allele)	67
		Insulin treatment	525	No association	68
		FBG response	228	No association	69
		HbA_{1c} response	97	Less reduction in HbA_{1c}	70
	TCF7L2	On treatment HbA_{1c} $<$7%	901	OR 1.9 for treatment failure (homozygous for variant allele)	164
		On treatment HbA_{1c} $<$7%	189	OR 1.6 for treatment failure (per variant allele)	165
Metformin					
Pharmacokinetic	*SLC22A1*	HbA_{1c} response	102	0.3% absolute lower reduction in HbA_{1c} (per variant allele)	166
		HbA_{1c} response	371	1.1% absolute lower reduction in HbA_{1c} (per variant allele)	77
		On treatment HbA_{1c} $<$7%	1,531	No association	76
		Drug intolerance	2,166	OR 2.4 for discontinuation (homozygous for variant alleles)	73
	SLC47A1	HbA_{1c} response	116	0.3% absolute lower reduction in HbA_{1c} (per variant allele)	167
		HbA_{1c} response	371	No association	77
		Risk of type 2 diabetes	2,994	Less reduction in diabetes risk	
	SLC47A2	HbA_{1c} response	253	0.1% absolute lower reduction in HbA_{1c} (any variant allele)	168
		HbA_{1c} response	371	No association	77
GWA studies	*ATM*	HbA_{1c} response, on treatment HbA_{1c} $<$7%	2,896	0.1% absolute greater reduction in HbA_{1c} and OR 1.4 for treatment success (per variant allele)	80
		HbA_{1c} response, on treatment HbA_{1c} $<$7%	1,366	No association with HbA_{1c} response, OR 1.2 for treatment success (per variant allele)	81

FBG, fasting blood glucose. *Loss-of-function variants rs757110 in *ABCC8* and rs5219 in *KCNJ11* are in near-complete linkage disequilibrium. **Effect listed only if reported as statistically significant in cited article.

(68,74–77). Unfortunately, this low replication rate is consistent with the rate in other candidate gene studies, which may be as low as 1–3% (78,79). The potential reasons include small sample sizes, heterogeneity of genetic architecture across different populations, and publication bias. In contrast, large GWA studies that use rigorous, prespecified statistical methods have produced more valid and reproducible results. For example, the only GWA study of treatment response to a diabetes therapy, conducted in a Scottish observational cohort with nearly 3,000 participants, identified a locus for glucose-lowering response to metformin near the *ATM* gene that met a stringent threshold for statistical significance (80), and this finding has replicated in other populations (81). Well-powered pharmacogenomic studies that use rigorous statistical methods may identify genetic variants that result in greater glucose-lowering effects or fewer adverse effects from other diabetes therapies.

GWA studies rely on information about the nonrandom association of alleles (linkage disequilibrium) to "tag" common and low-frequency variation throughout the genome in a subset of directly genotyped variants. Because these studies have identified only a small portion of the known heritability of most complex traits (82) and because theory predicts that rare variants are more likely to be damaging to gene function than common variants (83,84), there has been growing interest in studying rare variants. Advances in technology and informatics have made possible the high-throughput sequencing of whole exomes and whole genomes, which provide a complete assessment of both common and rare variation (85). A recent study that sequenced 202 genes encoding drug targets in 14,000 individuals identified on average one rare variant per 17 base pairs, and 90% of these variants were newly discovered (86). Another exome-sequencing study of 12 *CYP* genes, which are responsible for about 75% of all known oxidative drug metabolism, identified 1,006 variants in these genes and found that 73% were rare, a third were predicted to affect protein structure, and 9% of individuals had at least one newly discovered functional variant (87). Whether this abundance of rare variation explains some of the interindividual variability in drug response is unknown at this time, but the topic merits further evaluation.

CHALLENGES IN CONDUCTING GENOMIC RESEARCH

Study Power and Sample Size

One major barrier to genomic discovery in diabetes research has been the limited power to detect associations, which is a function of the frequency of the genetic variant, the magnitude of the effect to be detected, and the sample size (88). Large GWA studies with study populations of tens of thousands or more have helped to unravel the biology underlying many complex diseases, but most genetic loci identified by these studies have small effects. For example, the largest GWA study of type 2 diabetes, which included nearly 35,000 case and 115,000 control subjects, identified 65 genetic loci; all but the *TCF7L2* locus had ORs of 1.2 or lower per copy of the variant allele (15).

In pharmacogenomic studies, restriction to users of a particular drug further limits the available study population (89). Rare immune-mediated adverse drug reactions (ADRs) such as drug-induced liver injury or severe skin reactions may be caused by pathogenic variants with ORs of 100 or greater, and these associations can be detected with fewer than 50 cases (90–92). For diabetes therapies, rare adverse effects such as metformin-associated lactic acidosis or ketoacidosis related to sodium–glucose cotransporter 2 inhibitors may be amenable to pharmacogenomic discovery in similarly small studies.

It has been more difficult to identify pharmacogenomic associations with complex phenotypes such as myocardial infarction or stroke (93) or with quantitative traits such as QT interval prolongation or cholesterol lowering. For example, a large GWA study with over 30,000 participants from 10 observational cohorts evaluated QT interval prolongation from various drugs and failed to identify any pharmacogenomic loci at genome-wide levels of significance (94), and a GWA study with over 40,000 statin-using participants discovered and replicated two new loci for LDL cholesterol lowering, but each variant allele resulted in a relative change in LDL lowering effect of less than 2% (95). While these sorts of findings may reveal new information about human population biology, these effect sizes, which cannot be distinguished from intraindividual variation or measurement error in individual patients, are so small that the effort to genotype these variants can be safely omitted from clinical practice. As pharmacogenomic efforts move to whole-exome and whole-genome sequencing, even larger sample sizes may be required to identify associations with rare variants.

Individual pharmacogenomic variants often have small effects or fail to reach stringent thresholds of statistical significance, but they can be combined within a gene or within a pathway of several genes to identify clinically important effects. As an example, Dujic et al. (73) evaluated the relationship between metformin intolerance and four reduced-function variants in the gene *SLC22A1*, which transports metformin into the intestine and may mediate some of the gastrointestinal side effects from this drug. They found that the presence of any two reduced-function alleles increased the risk of metformin discontinuation by 2.4-fold (73).

To assess associations with the large number of variants identified by whole-exome and whole-genome sequencing, more innovative approaches are necessary. Annotation tools have been used to restrict analyses to variants that are likely to be functional, on the basis of expected protein structure, associations with gene expression levels (96,97), and information from the Encyclopedia of DNA Elements (ENCODE) project, which has systematically mapped nonprotein coding regulatory function—including transcription factor binding sites, chromatin structure, and histone modifications—throughout the genome (98). Various statistical methods have been developed that aggregate rare functional variants for gene-based association tests, which can improve the power to detect an association if there are multiple damaging variants within a gene (99,100). Data from whole-exome and whole-genome sequencing have not yet been systematically evaluated in pharmacogenomic studies, but for some complex traits these methods have been used to identify rare variants with large effects, both in new and previously unidentified loci (101).

The studies of statin response and drug-induced QT prolongation described in the preceding paragraphs represent one model for conducting genomic research in large populations: local analysis of deeply phenotyped cohorts followed by a meta-analysis of summary results in large research consortia (15,102). The increasing availability of electronic health data and a recognition of the large sample sizes required for genomic discovery research have led to the emergence of another model: biobank studies that genotype tens or hundreds of thousands of individuals and link these genetic data with participants' electronic health data to create large data repositories. Some of these studies include a baseline visit for physical measurements, the collection of specimens, and imaging tests (103,104), similar to the traditional cohort studies, and they all rely on electronic health databases for longitudinal information on health care encounters, laboratory tests, vital status, and medication use. Two of the largest biobank studies, the Million Veteran Program (105) and the UK Biobank (104), have recruited close to 500,000 individuals each.

Phenotyping With Electronic Health Data

Electronic health data have been immensely useful for research, but they have important limitations. Results from laboratory tests that are measured in the course of clinical care, such as HbA_{1c} or cholesterol levels, are likely to be recorded accurately and completely, but they may be related to the clinical indications for the tests and lack standardization across sites. Diagnosis codes associated with health care encounters, an important source of information about disease status, are assigned for clinical and billing rather than research purposes; geographic location (106), changes in reimbursement (107,108), and other factors can influence the assignment of these codes. For a given study design, different databases can produce different estimates of association between a drug exposure and a health outcome, sometimes in opposite directions (109). Nonetheless, diagnosis code–based algorithms have been used to identify some acute diabetes complications, such as hypoglycemia (110,111) and myocardial infarction

(112,113), with a reasonably high degree of accuracy (positive predictive value [PPV] 80–90%).

For other diabetes complications, such as heart failure, the accuracy of a diagnostic algorithm may vary substantially by the diagnosis code used and even the position of the code (primary vs. secondary) (114,115). The use of low-PPV algorithms can attenuate estimate of associations toward the null (116), sometimes dramatically. When a new diagnosis code was introduced for rhabdomyolysis, a severe ADR related to statin use, we evaluated the accuracy of this code in a large health care system by reviewing electronic medical records to validate potential cases, and we estimated the risk of rhabdomyolysis associated with the 80-mg dose of simvastatin, which was known to be high from a recent RCT (117). The PPV of the rhabdomyolysis code for the statin-related ADR was only 8%. Moreover, the relative risk for rhabdomyolysis associated with high-dose versus low-dose simvastatin was 12.2 when validated cases were evaluated, replicating the RCT estimate, but only 1.8 when the diagnosis code was used without validation (118). This marked attenuation of a genuine association is not an isolated finding; the quality (119) and severity (120) of disease phenotypes have also been shown to impact the magnitude of pharmacogenomic associations. For studies that evaluate genetic associations with disease outcomes, including ADRs, it may sometimes be necessary to conduct validation studies to assess the accuracy of claims-based data (121). Despite these limitations, the linkage of genomic data with electronic health data in large study populations holds promise as a powerful tool for research.

FRAMEWORK FOR EVALUATING A GENOMIC TEST

For the regulatory approval of new therapies directed at specific genetic defects, such as ivacaftor for the treatment of cystic fibrosis caused by a specific *CFTR* mutation (122), the U.S. Food and Drug Administration (FDA) requires the same standard used to evaluate all new drugs: substantial evidence of efficacy and safety from well-controlled studies, typically rigorously conducted RCTs. For therapies already in use that have demonstrated efficacy and safety in nongenetically determined populations, the evidence standard for using genomic information to select the best drug or dose is less certain. The FDA currently includes pharmacogenomic information in the prescribing information for over 160 drugs (123), but its oversight of laboratory-developed genetic tests is concerned primarily with analytic validity (i.e., ability to reliably measure a genetic variant or a biomarker) (124), which is inadequate to guide treatment decisions. A recent study of pharmacogenomic information in drug labels found convincing evidence of clinical validity (i.e., how accurately and consistently genetic variation predicts a phenotype) for only 36% of these drugs, and evidence of clinical utility (i.e., ability to improve outcomes for patients) for only 15% (125). The Centers for Disease Control and Prevention Office of Public Health Genomics has developed a more comprehensive framework for the evaluation of a genetic test that includes questions about analytic validity, clinical validity, and clinical utility, as well as ethical, legal, and social implications (ACCE), which are summarized in Table 3 (126,127). These standards are important to protect the health of the public.

As described earlier, most reported pharmacogenomic findings fail to replicate and therefore lack clinical validity. Similarly, rare variants identified by sequencing and initially identified as “pathogenic” are often downgraded to “uncertain significance” or “benign” after further study (128,129). For example, in the FHS and the Jackson Heart Study (JHS), seven genes responsible for MODY were sequenced and rare variants were identified that had previously been identified as causal for MODY or were predicted to be damaging to protein function by using annotation tools. These variants, present among 2% of persons in these population-based cohorts, were not associated with the risk of diabetes, and only one variant carrier out of 68 met the criteria for MODY (130).

Of the genomic findings for diabetes that have clinical validity, most have effects on disease outcomes or surrogate end points that are uncertain or too small to be clinically meaningful. Genetic risk panels for the prediction of type 2 diabetes are one example (131). Another example is the *ATM* locus for metformin treatment response, the most widely replicated diabetes pharmacogenomic finding; each copy of the variant allele was associated with only a 0.1% greater reduction in HbA_{1c} (81). Even if patients had whole-genome sequence data already available in their medical records, this treatment effect is still too small to be clinically useful. For MODY, which often has a clear genetic cause, most cases appear to be undiagnosed, in part because of uncertainty from clinicians about the clinical benefits of genetic testing (132). Making treatment decisions based on genetic tests that lack clinical validity, clinical utility, or both can have unintended consequences, including withholding beneficial treatments, an unnecessary increase in costs, or the use of drugs with harmful effects.

For examples of actionable genetic tests that meet the criteria for clinical validity and clinical utility, areas of medicine other than diabetes are instructive. Abacavir is a first-line treatment for HIV that is effective and well tolerated in most people, but about 5% of persons exposed to this drug develop a serious hypersensitivity reaction characterized by rash, fever, and damage to multiple organ systems (133). Initial studies of men of mostly European ancestry identified the cause of this ADR to be the *HLA-B*57:01* variant (91,134), with an OR of well over 100 (119), and this finding was later extended to other populations (135). A double-blind RCT demonstrated that genetic testing for the *HLA-B*57:01* variant prevented all cases of abacavir-induced hypersensitivity (136), and genetic testing is now routinely conducted before initiating treatment with this drug.

For another severe immune-mediated ADR, the translation of genetic testing into practice followed a different course. Stevens-Johnson syndrome/toxic epidermal necrolysis (SJS/TEN) related to carbamazepine use was found to be strongly associated with the *HLA* variant *HLA-B*15:02* in several Asian populations (92,137), and screening for this variant can effectively prevent the ADR (137). In 2008, Hong Kong instituted a policy of routine genetic screening before initiating carbamazepine treatment, but providers simply avoided prescribing this medication and instead prescribed other antiepileptic drugs that can also cause

Table 3—ACCE criteria for the implementation of a genetic test

	Key questions	Example applications to diabetes
Analytic validity	How often does the genetic test fail to give a useable result?	For a GRS for type 2 diabetes risk, how often does the test result in a genotype at each locus?
	What is the sensitivity and specificity of the test for a genetic variant?	For the rare *HNF1A* missense variant associated with diabetes risk, how often does the test detect the variant when it is present and how often does the test result in a false positive when the variant is not present?
	What is the within- and between-laboratory precision?	Are standardized methods used in different laboratories? How does the accuracy of the test vary from laboratory to laboratory?
	Is confirmatory testing required?	When a pathogenic variant in a MODY gene is identified from high-throughput sequencing, is confirmatory genotyping by another method required?
Clinical validity	What is the quality of the disease phenotype or treatment response measurement? What is the quality of the study designs used to evaluate these outcomes?	For a GRS that discriminates type 1 from type 2 diabetes, are standardized definitions of diabetes type used? Was the study design cross-sectional or longitudinal?
	What is the prevalence of the phenotype or the distribution of treatment response in the studied populations?	For a pharmacogenomic test for metformin treatment response, how is treatment failure/success defined and what is the rate of treatment failure/success in the studied population?
	What is the sensitivity and specificity of the test for the disease phenotype or treatment response? What is the magnitude and precision of the genotype-phenotype relationship?	What is the relative change in HbA_{1c} lowering associated with the *ATM* locus for metformin treatment response?
	What are the genetic or environmental modifiers of the genotype-phenotype relationship?	Do diabetes severity, obesity, the use of additional drug therapies, or other factors modify the pharmacogenomic associations for metformin treatment response?
	Has the test been adequately validated on all populations in which it may be offered?	For a GRS for type 2 diabetes risk, has the test been validated among obese individuals and among persons from different racial/ethnic populations?
Clinical utility	What is the impact of a positive or negative test on patient care in terms of health outcomes?	What is the absolute change in HbA_{1c} lowering associated with the *ATM* locus for metformin treatment response? Does this pharmacogenomic test result in projected or tangible health benefits in terms of clinical complications, such as a reduced risk of blindness or cardiovascular disease?
	What are the financial costs associated with testing and the economic benefits associated with actions resulting from testing?	What is the cost to test for the common *TCF7L2* variant for type 2 diabetes risk, including laboratory, reporting, educational, and counseling costs? What is the cost per case of diabetes predicted? Does this test result in cost-effective screening or prevention of diabetes later in life?
	What educational materials for patients have been developed and validated?	Do educational materials clearly explain the magnitude of the increased risk of type 2 diabetes associated with the common *TCF7L2* variant in relation to other known risk factors?
Ethical, legal, and social implications	What is known about how this test could lead to stigmatization, discrimination, privacy/confidentiality, and personal/family social issues?	Does the identification of a pathogenic variant responsible for a hereditary form of early-onset diabetes have implications for family planning?
	Are there legal issues regarding consent, ownership of data and/or samples, patents, licensing, proprietary testing, disclosure, or reporting requirements?	Are physicians providing sufficient information about the potential risks and benefits from genetic testing so that patients can make informed decisions?
	What safeguards have been described and are these safeguards effective?	

Adapted from refs. 126,127.

severe skin reactions. As a result, the overall rate of SJS/TEN in Hong Kong did not change (138). This unintended result of a policy decision on a genetic test with clinical validity and clinical utility demonstrates that other concerns, such as convenience or cost, may influence the harms or benefits for a population.

Even for well-replicated pharmacogenomic findings with large effects, there can be disagreement about what constitutes clinical utility. Warfarin is an anticoagulant drug that is notoriously difficult to dose because of wide interindividual variability in the anticoagulant effect, much of which is explained by variation in the pharmacokinetic genes *CYP2C9* and *VKORC1*. The benefits of testing for variants in these genes have even been evaluated in three large well-designed RCTs, two of which demonstrated that genetic testing resulted in a shorter time to therapeutic effect but no reduction in thrombotic or bleeding complications (139–141). Opinions differ about whether pharmacogenomic testing has a role in warfarin treatment (142–144), and there has been a broader debate about whether RCTs are required to demonstrate the utility of a genetic test (79,145,146). Nonetheless, genetic testing for warfarin treatment has been minimal in practice. In the absence of consistent recommendations about when to use genetic information in prescribing and other treatment decisions, health care providers, patients, and also payers and health care systems will have an important voice in this discussion.

ADDITIONAL BARRIERS TO THE IMPLEMENTATION OF GENOMICS

The implementation of genomics in practice has generally involved a decision about whether to order a genetic test before starting a new treatment. For patients who have already undergone preemptive genotyping or sequencing, which is not yet common but likely to increase in the future (147–149), the decision may be about whether to use a patient's existing genetic information to guide treatment. With either approach, the main barrier to the implementation of genomics for diabetes care at this time is a robust lack of actionable findings in the areas of diabetes and cardiovascular medicine. There are also practical issues that must be addressed, which include the storage and integration of complex genomic data into the electronic health record, the interpretation of these data in an accessible format, and the creation of clinical decision support (CDS) tools that aid health care providers in using this information to make treatment decisions at the point of care (150). Various groups have made important contributions in developing model systems that address these problems (147,148,151,152).

CDS tools, which have been in use for many years for diabetes management, provide automated testing or treatment recommendations based on information in the electronic health record (153). The CDS tools for genomics that are under development rely on externally curated data resources, such as PharmGKB (154) and ClinVar (155), to determine which potentially actionable variants to incorporate and how to translate genotypes into expected phenotypes. PharmGKB currently includes information about pharmacogenomic associations for metformin and sulfonylureas; however, none of the associations meet the criteria for the highest level of evidence, and there is no recommendation for pharmacogenomic testing for these drugs (156). In drug-specific evidence summaries and guidelines, the Clinical Pharmacogenetics Implementation Consortium has begun to provide standardized terms, sample text for electronic health record documentation and point of care alerts, and clinical implementation workflows, which will be a valuable resource as the role of pharmacogenomics expands in clinical practice (157,158).

The increasing availability of CDS tools and online databases with information on actionable genomic findings will facilitate the use of genomic testing for diabetes by clinicians. However, because most clinicians are not yet comfortable using genomic information to make clinical decisions (159,160), improved education for both trainees and practicing clinicians is needed, and opportunities for both are improving (161,162). Professional societies and specialty boards will play an important role in the integration of genomics in physician training and continuing medical education; credentialing requirements for ordering genomic tests could help to ensure that such tests are used appropriately (163). If the use of genomic information ultimately proves useful in the care of patients with diabetes, even with adequate educational and training opportunities for clinicians, financial incentives may be required to spur widespread implementation, as was the case with the increased adoption of electronic health records after legislation was passed that provided reimbursements to hospitals and providers for this purpose (9–11).

CONCLUSIONS

At this time, there are few if any actionable genomic findings for diabetes that are ready for implementation. However, the increasing availability of genomic data in large populations linked with electronic health data may become a powerful resource for genomic discovery, and examples from other areas of medicine offer lessons about the limitations of these data that can help guide the direction of future research. Whether genomic information should be used in clinical practice requires a framework for evaluating the validity and clinical utility of this approach, an improved integration of genomic data into electronic health records, and the clinical decision support and educational resources for clinicians to use these data. Efforts to identify optimal approaches in all of these domains are creating a growing body of evidence that may help to bring diabetes into the era of genomic medicine.

Funding. J.S.F. was supported by National Heart, Lung, and Blood Institute grant K08HL116640.

Funding agencies did not influence the design and conduct of the study, collection, management, analysis, and interpretation of the data or preparation, review, or approval of the manuscript.

Duality of Interest. B.M.P. serves on the Data and Safety Monitoring Board of a clinical trial of a device funded by the manufacturer (Zoll LifeCor) and on the Steering Committee of the Yale University Open Data Access Project funded by Johnson & Johnson. No other potential conflicts of interest relevant to this article were reported.

Received 28 April 2020; revised 24 August 2020; editorial decision 21 December 2020; accepted 5 January 2021

Aims The aim of this study was to use human genetics to investigate the pathogenesis of sick sinus syndrome (SSS) and the role of risk factors in its development.

Methods and results We performed a genome-wide association study of 6469 SSS cases and 1 000 187 controls from deCODE genetics, the Copenhagen Hospital Biobank, UK Biobank, and the HUNT study. Variants at six loci associated with SSS, a reported missense variant in *MYH6*, known atrial fibrillation (AF)/electrocardiogram variants at *PITX2, ZFHX3, TTN/CCDC141*, and

SCN10A and a low-frequency (MAF = 1.1–1.8%) missense variant, p.Gly62Cys in *KRT8* encoding the intermediate filament protein keratin 8. A full genotypic model best described the p.Gly62Cys association ($P = 1.6 \times 10^{-20}$), with an odds ratio (OR) of 1.44 for heterozygotes and a disproportionally large OR of 13.99 for homozygotes. All the SSS variants increased the risk of pacemaker implantation. Their association with AF varied and p.Gly62Cys was the only variant not associating with any other arrhythmia or cardiovascular disease. We tested 17 exposure phenotypes in polygenic score (PGS) and Mendelian randomization analyses. Only two associated with the risk of SSS in Mendelian randomization, AF, and lower heart rate, suggesting causality. Powerful PGS analyses provided convincing evidence against causal associations for body mass index, cholesterol, triglycerides, and type 2 diabetes ($P > 0.05$).

Conclusion We report the associations of variants at six loci with SSS, including a missense variant in *KRT8* that confers high risk in homozygotes and points to a mechanism specific to SSS development. Mendelian randomization supports a causal role for AF in the development of SSS.

Summary of genetic insight into the pathogenesis of SSS and the role of risk factors in its development. Variants at six loci (named by corresponding gene names) were identified through GWAS and their unique phenotypic associations provide insight into distinct pathways underlying SSS. Investigation of the role of risk factors in SSS development supported a causal role for AF and heart rate and provided convincing evidence against causality for BMI, cholesterol (HDL and non-HDL), triglycerides and T2D. Mendelian randomization did not support causality for CAD, ischaemic stroke, heart failure, PR interval or QRS duration (not shown in figure). Red and blue arrows represent positive and negative associations, respectively.

Keywords Sick sinus syndrome • GWAS • *KRT8* • Mendelian randomization • Atrial fibrillation

Introduction

Sick sinus syndrome (SSS) is a complex cardiac arrhythmia and the leading indication for permanent pacemaker implantation worldwide.[1] It is characterized by pathological sinus bradycardia, sinoatrial block, or alternating atrial brady- and tachyarrhythmias. Symptoms include fatigue, reduced exercise capacity, and syncope.[2,3] Few studies have been conducted on the basic mechanisms of SSS

Downloaded from https://academic.oup.com/eurheartj/advance-article/doi/10.1093/eurheartj/ehaa1108/6134552 by Medicinsk Bibliotek, Aalborg Sygehus SYD user on 11 March 2021

and therapeutic limitations reflect an incomplete understanding of the pathophysiology. No specific treatment option is aimed at underlying pathways and trying to determine who benefits from cardiac pacing can be challenging.[4] A better understanding of mechanisms leading to SSS is crucial for improvements in treatment and prevention and genetic studies provide an opportunity to gain such insight.

Coding variants in several genes, including *HCN4, SCN5A*, and *GNB2*, have been implicated in rare familial SSS through linkage analysis and candidate gene methods.[5–15] In the only published genome-wide association study (GWAS) of SSS to date, we identified a strong association with a missense variant in *MYH6*, encoding the alpha-heavy chain subunit of cardiac myosin. This was the first GWAS discovery implicating a cardiac structural or contractile unit as a primary cause of arrhythmia.[16]

Age is the strongest risk factor for SSS,[17] potentially reflecting degenerative fibrosis and electrical remodelling of the SA node and the atria in general.[18–20] SSS often coexists with the more common atrial fibrillation (AF)[21] and the two arrhythmias are thought to predispose to each other.[22] We have previously examined the role of AF in SSS development through Mendelian randomization,[23] a method using sequence variants associated with a risk factor (AF) as unbiased proxy indicators to determine whether the risk factor can cause a disease (SSS).[24,25] The study supported causality,[23] likely mediated through atrial remodelling.[26,27] Several other traits have been associated with SSS while the nature of the associations has not been ascertained. These include body mass index (BMI), height, heart rate, and cardiovascular diseases such as hypertension, myocardial infarction, heart failure, and stroke.[17]

To gain insight into the pathogenesis of SSS, we performed a large GWAS of over 6000 cases and one million controls of European descent. We used polygenic scores (PGSs) and Mendelian randomization to determine the nature of the associations of risk factors with SSS and in particular whether they contribute to the cause of the disease.

Methods

The study design is two-fold (Supplementary material online, *Figure S1*). First, we performed a meta-analysis of GWASs, searching for associations of sequence variants with SSS. In total 6469 SSS cases were compared to 1 000 187 controls in a meta-analysis of material from deCODE genetics Iceland, the Copenhagen Hospital Biobank Cardiovascular Study (CHB-CVS)/Danish Blood Donor Study (DBDS), and the UK Biobank,[28] with follow-up in the Norwegian Nord-Trøndelag Health Study (HUNT).[29] Second, we performed PGS analysis and Mendelian randomization to examine the role of putative risk factors in SSS development (for detailed methods, see Supplementary material online).

Sick sinus syndrome study populations

The deCODE genetics SSS sample consisted of 3577 Icelanders diagnosed with SSS and 347 764 controls. The CHB-CVS included 2209 SSS cases. The control group included blood donors from the DBDS ($N > 99\ 000$)[30] and SSS cases were also compared to subjects in CHB-CVS with other cardiovascular conditions ($N > 89\ 000$). The SSS population from the UK Biobank consisted of 403 cases and 403 181 controls.[28] The HUNT cohort consisted of 280 Norwegian SSS cases and 69 141 controls recruited through a population-based health survey conducted in the Nord-Trøndelag County, Norway.[29] In all four cohorts, SSS diagnosis was based on International Classification of Diseases 9th (ICD-9: 427.8) or 10th revision (ICD-10: I49.5) from hospitals and/or outpatient clinics. The cohorts are described in more detail in Supplementary material online, Methods and Supplementary material online, *Table S1*.

Genotyping

The deCODE study was based on whole-genome sequence data from 28 075 Icelanders participating in various disease projects. The 32.9 million variants that passed quality threshold were imputed into 127 175 Icelanders who had been genotyped using Illumina SNP chips. Finally, genotype probabilities for untyped relatives were calculated based on Icelandic genealogy.[31] Genotyping for CHB-CVS and DBDS was performed at deCODE using a north European sequencing panel of 15 576 individuals (including 8429 Danes) for imputation into those chip typed (methods manuscript in preparation). Genotyping in the UK Biobank has been described in detail elsewhere.[32–35] Illumina HumanCoreExome arrays were used for genotyping in the HUNT cohort.

Genome-wide association study: statistical analysis

We performed a meta-analysis of GWAS of 6189 SSS cases and 931 046 controls from deCODE genetics, CHB-CVS/DBDS, and the UK Biobank. We then tested genome-wide significant and suggestive variants (Supplementary material online, Methods) among 280 cases and 69 141 controls from the Norwegian HUNT study. We used logistic regression to test for association between sequence variants and SSS and other case–control phenotypes, treating phenotype status as the response and allele count as a covariate. Other available individual characteristics that correlate with phenotype status were included in the model as nuisance variables. SSS associations were tested under additive, recessive, and full genotypic models. The full genotypic model includes separate parameters for heterozygotes and homozygotes. We corrected the threshold for genome-wide significance for multiple testing with a weighted Bonferroni adjustment using as weights the enrichment of variant classes with predicted functional impact among association signals estimated from the Icelandic data.[36] Significance thresholds were 1.3×10^{-7} for variants with high impact, 2.6×10^{-8} for variants with moderate impact (including missense), 2.4×10^{-9} for low-impact variants, 1.2×10^{-9} for other variants in Dnase I hypersensitivity sites, and 7.5×10^{-10} for all other variants.[36] We used linear regression to test variant associations with quantitative phenotypes, treating the quantitative measurement as response and the genotype as covariate. These included endophenotypes of SSS, chronotropic response to exercise ($N = 7746$), and electrocardiogram (ECG) measurements ($N \sim 73\ 000$) (see Supplementary material online, Methods for detail).

Analysis of genetic risk shared by sick sinus syndrome and putative risk factors

We used PGSs for 17 exposure phenotypes to examine their correlation with SSS (Supplementary material online, *Table S2*). The phenotypes were chosen because of reported epidemiological associations with SSS or other cardiovascular conditions (see Supplementary material online, Methods). The PGSs were generated using summary statistics from the largest available GWASs (training sample) for each phenotype that do not include deCODE data (Supplementary material online, *Table S2* and Supplementary material online, *Figure S1*). Subsequently, they were tested for association with the risk of SSS among 2556 chip-typed individuals from deCODE (target sample). *P*-values were corrected using genomic control.[37]

The use of PGSs to detect association between exposure and outcome is a robust method such that the absence of association in a well-powered PGS analysis provides strong evidence against causality.[25]

CI, confidence interval; OR, odds ratio.

[a] Effect allele frequency in Iceland (deCODE).

[b] Variant exclusive to Iceland.

[c] p.Thr811Ile in *TTN* and p.Glu382Asp in *CCDC141* are weakly correlated: $R^2 = 0.20$, $D' = 0.64$.

However, finding association in PGS analysis does not confirm causality.[38,39] For the eight PGSs that associated with SSS, we performed a 2-sample Mendelian randomization analysis, equivalent to a fixed effect MR-Egger[40] using published genome-wide significant SNPs from the largest available GWAS on each exposure phenotype as genetic instruments.[41–49] To estimate the causal effect, we regressed the published effects of the SNPs on the respective exposure phenotype against their SSS effects in deCODE, CHB-CVS/DBDS, and the UK Biobank, using minor allele frequency (MAF) × (1 - MAF) as weights. For the ECG measurements PR interval and QRS duration, effects in milliseconds were converted to standard deviations (SDs) according to one SD in the Icelandic data so that all causal estimates in a Mendelian randomization forest plot correspond to equal odds ratio (OR) or SD changes for binary and quantitative traits, respectively. For significant associations, we performed further sensitivity analysis to detect outliers (funnel plots) and tested for directional pleiotropy using the MR-Egger intercept test (see Supplementary Material online, Methods).[40]

Results

Six sick sinus syndrome loci

In a GWAS comparing 6469 SSS cases to 1 000 187 controls, variants at six loci satisfied our criteria for genome-wide significance (*Table 1*, Supplementary material online, *Table S3*, Figure 1, and Supplementary material online, *Figure S2*), with ORs ranging from 1.12 to 8.88. One is at a novel SSS locus, a low-frequency missense variant, p.Gly62Cys (MAF = 1.1–1.8% in the four cohorts) in the gene *KRT8* on chromosome 12. This variant has not been associated with arrhythmias or ECG traits before. The other variants are the rare Icelandic SSS missense variant p.Arg721Trp in the sarcomere gene *MYH6*,[16] common variants at two AF loci, *PITX2*[50] and *ZFHX3*,[51] and two ECG loci, *TTN/CCDC141*[52] and *SCN10A*.[52–54] We have previously reported secondary associations of variants at the four AF and ECG loci with SSS.[23,52] At the *TTN/CCDC141* locus, we report associations of two missense variants, p.Thr811Ile in *TTN* and p.Glu382Asp in *CCDC141*, that are weakly correlated ($R^2 = 0.20$, $D' = 0.64$, Supplementary material online, *Table S4*).

High penetrance of sick sinus syndrome among homozygotes for p.Gly62Cys in *KRT8*

The SSS association of p.Gly62Cys in *KRT8* was discovered with the additive model (*Table 1* and Supplementary material online, *Tables S5 and S6*). However, homozygotes of p.Gly62Cys have a higher risk of SSS than assumed under the additive model (*Table 2*, homozygous genotypic OR > $1.62^2 = 2.62$, $P_{\text{full vs. additive}} = 2.1 \times 10^{-8}$). We observed an OR of 1.44 for heterozygotes (95% CI = 1.26–1.65) and 13.99 for homozygotes (95% CI = 8.16–23.98), compared to non-carriers (*P*-value for the full genotypic model = 1.6×10^{-20}, *Table 2*). None of the other SSS associations deviated from the additive model ($P > 0.05$). *KRT8* encodes the intermediate filament keratin 8 (K8, Supplementary material online, *Figure S3*) which is widely expressed, including in the heart,[55] and we detected its expression (52.1 ± 30.2 transcripts per million) in our cardiac samples from right atria ($n = 169$, Supplementary material online, Methods). Neither p.Gly62Cys nor two correlated variants ($R^2 > 0.6$) associated with

Downloaded from https://academic.oup.com/eurheartj/advance-article/doi/10.1093/eurheartj/ehaa1108/6134552 by Medicinsk Bibliotek, Aalborg Sygehus SYD user on 11 March 2021

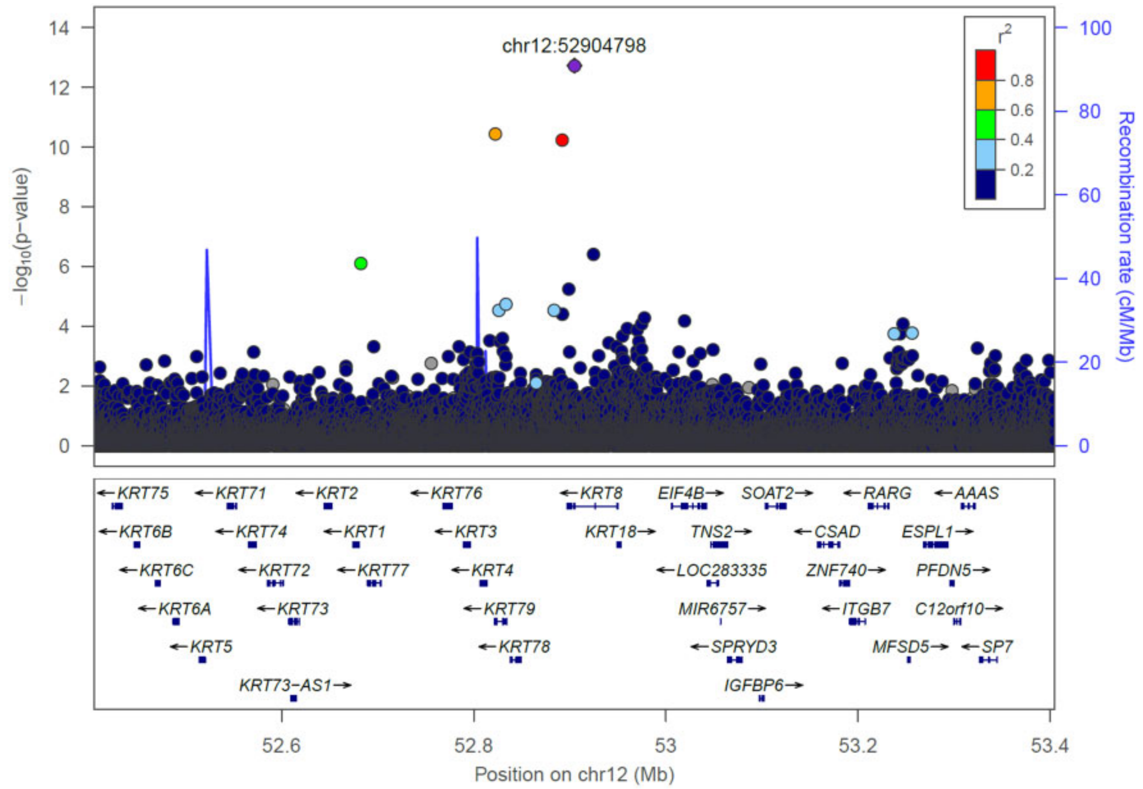

Figure 1 Regional plot of the *KRT8* locus on chromosome 12q13. The plot depicts association results (*P*-values) with SSS ($N = 6189$) in a meta-analysis with data from deCODE, the CHB-CVS/DBDS, and the UK Biobank. The *y*-axis shows the -$\log_{10}$ *P*-value and *x*-axis shows the genomic position (hg38). The lead variant of the signal (p.Gly62Cys) is labelled as a diamond and coloured purple. Other variants are coloured according to correlation (R^2) with the lead variant in the deCODE data. The plot includes variants common to the three datasets as well as variants specific to the Icelandic deCODE data.

the expression of *KRT8* or nearby genes (1 Mb) in our cardiac samples (Supplementary material online, *Table S7*) or in GTEx.[55]

About 1 in 5000 individuals from the four European populations in this study is homozygous for p.Gly62Cys in *KRT8*, consistent with the Hardy–Weinberg equilibrium ($P = 0.071$–0.82). To evaluate the penetrance of SSS among homozygous carriers of p.Gly62Cys, we analysed the two largest SSS datasets in the study, deCODE and CHB-CVS/DBDS. Considering that SSS is a late onset disease, the observed penetrance is relatively high although incomplete (*Figure 2*). Eight out of 36 genotyped Icelandic homozygotes (aged 23–88 years, mean 59.9) had SSS (Supplementary material online, *Table S8*) and 10 out of 79 homozygotes (aged 27–103 years, mean 62.1) in CHB-CVS/DBDS. Homozygotes were not significantly younger at SSS diagnosis than heterozygotes or non-carriers ($P = 0.53$ in deCODE and $P = 0.26$ in CHB-CVS/DBDS, Supplementary material online, *Table S9*).

Diverse associations of sick sinus syndrome variants with other phenotypes

We tested the associations of the SSS variants with other phenotypes in deCODE, CHB-CVS/DBDS, and the UK Biobank datasets (Supplementary material online, *Tables S10–S14*). In addition to SSS, p.Gly62Cys in *KRT8* associated with pacemaker implantation (OR heterozygotes = 1.28, 95% CI = 1.13–1.45, OR homozygotes = 9.17, 95% CI = 2.89–29.09, $P = 1.9 \times 10^{-8}$). The variant did not associate with other arrhythmias or cardiovascular diseases, with electrolyte or hormonal disturbances that are linked to the development of SSS (potassium, calcium, thyroid stimulating hormone)[57] or with the suggested consequence of p.Gly62Cys in candidate gene studies[58] (pancreatitis/lipase, liver disease, Bonferroni-adjusted significance threshold of $P = 0.05/23 = 0.0022$, Supplementary material online, *Tables S10 and S11*). Furthermore, p.Gly62Cys did not associate with any of the 122 ECG parameters (*N* up to 72 825, Supplementary material online, *Table S13*).

The associations of SSS variants with AF varied. p.Gly62Cys in *KRT8* (Supplementary material online, *Tables S10 and S11*) and the missense variants in *TTN*/*CCDC141* (Supplementary material online, *Table S12*) did not associate with the risk of AF, applying a Bonferroni-corrected significance threshold of $P < 0.05/14 = 0.0036$. The *TTN*/*CCDC141* variants are located within 300 kbp from previously reported AF variants[41] and are independent of them ($R^2 < 0.2$, Supplementary material online, *Figure S4*). The other four SSS loci have been reported to affect AF but their pattern of association with the two phenotypes differ. p.Arg721Trp in *MYH6*[23] associates stronger with SSS than AF but the reverse applies to variants at *PITX2*. At

CI, confidence interval; EAF, effect allele frequency; OR, odds ratio; Pos, position; SSS, sick sinus syndrome.

[a] The full genotypic model ($P_{\text{full}} = 1.6 \times 10^{-20}$) deviates significantly from the additive model ($P_{\text{additive}} = 9.4 \times 10^{-14}$). *P* for deviation from the additive model = 2.1×10^{-8}.

[b] Among 14 homozygotes in the HUNT study, none had SSS (*P*-value for homozygotes = 0.97).

ZFHX3, the effects on AF and SSS are comparable.[41,50,51,59,60] p.Val1073Ala in *SCN10A* is one of the top AF variants at this locus (Supplementary material online, *Figure S5*), but the allele that increases the risk of SSS protects against AF (Supplementary material online, *Table S12*).[53,61]

All the SSS variants increased the risk of pacemaker implantation (Supplementary material online, *Tables S10–S12*), as expected since SSS is the most common reason for this procedure. We have previously described in detail the associations of p.Arg721Trp in *MYH6* with coarctation of the aorta, other congenital malformations of the heart, aortic valve stenosis, and heart failure[23,62,63] (Supplementary material online, *Table S12*). We note that p.Glu382Asp in *CCDC141* associated with both second- and third-degree atrioventricular block (AVB)[52] and the association with third-degree AVB was genome-wide significant ($P = 1.3 \times 10^{-14}$, OR = 1.27, 95% CI = 1.20–1.35) and more significant than the SSS association. Another notable association is that of the *PITX2* variant with heart failure (Supplementary material online, *Table S12*) as recently reported in a GWAS of heart failure.[47] None of the SSS variants associated with chronotropic response to exercise (Supplementary material online, *Tables S15 and S16*) in our dataset. However, the *SCN10A* and *CCDC141* loci have been reported to associate with heart rate profile during exercise in larger studies of UK Biobank data.[64,65]

Genetically predicted atrial fibrillation and lower heart rate associate with sick sinus syndrome

PGSs are powerful tools for detecting associations between phenotypes.[38] We generated PGSs for 17 exposure phenotypes using summary statistics from the largest available GWASs (Supplementary material online, *Table S2*) and tested them for association with SSS in deCODE data. Eight PGSs, for AF, heart rate, coronary artery disease (CAD), height, QRS duration, PR interval, ischaemic stroke, and heart failure, associated with SSS while those for BMI, type 2 diabetes (T2D), non-HDL cholesterol, HDL cholesterol, triglycerides, and hypertension/blood pressure traits did not (Bonferroni-adjusted significance threshold of $P = 0.05/17 = 0.0029$, Supplementary material online, *Table S17*). The PGS for heart rate was the only one to inversely associate with SSS risk.

We then performed Mendelian randomization to determine the causality of the associations between the eight exposures and SSS, using genome-wide significant SNPs from GWAS of the exposure phenotypes as instruments (see Methods). Genetic predisposition to AF and genetically determined heart rate and height associated with the risk of SSS but the height association did not remain after accounting for AF in a multivariate analysis (*Figures 3* and *4A* and *B*).[66–68] With few exceptions, the effects of AF variants on SSS are proportional to their effects on AF ($P = 7.8 \times 10^{-14}$, *Figure 4A* and Supplementary material online, *Figure S6A*). The greatest deviation from the expected SSS effect was for the association at *SCN10A* (tagged by rs6790693, OR for AF = 1.06, OR for SSS = 0.89, Supplementary material online, *Figure S6A*). Mendelian randomization did not support causality for CAD, ischaemic stroke, heart failure, PR interval, or QRS duration (*Figure 3* and Supplementary material online, *Figure S7*).

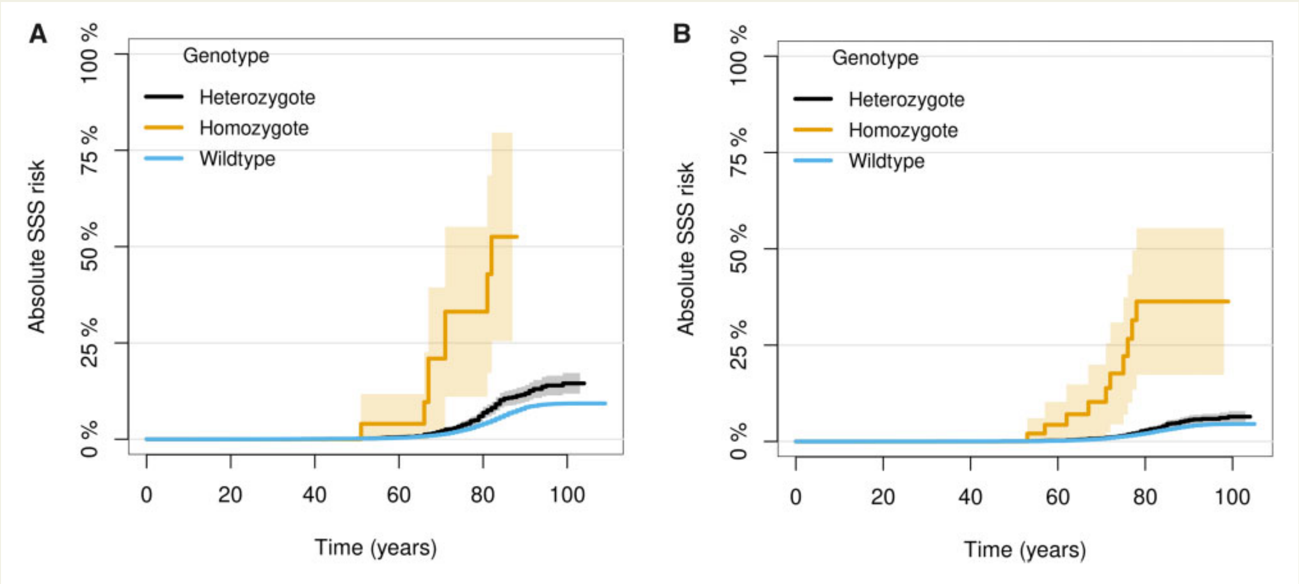

Figure 2 Cumulative incidence curves for SSS age of onset based on *KRT8* p.Gly62Cys genotype (*A*) in deCODE and (*B*) in CHB-CVS/DBDS. Aalen–Johansen estimator was used, treating death as a competing risk.[56] Age of onset was determined by the first registered ICD diagnosis of SSS available to us and thus represents an upper range (Supplementary material online, Methods).

Discussion

Traditionally, SSS has been considered as a collection of conditions with a variety of causes, intrinsic and extrinsic to the SA node.[69] In line with this notion, we identified sequence variants associating with SSS at six loci implicating several distinct pathways in SSS development. One of the SSS associations is novel, with a low-frequency missense variant, p.Gly62Cys in *KRT8*. One is with the reported p.Arg721Trp in *MYH6*,[16] and four confirm loci previously implicated in SSS secondarily to AF, at *PITX2*,[50] and *ZFHX3*,[51] or ECG traits, at *SCN10A*[53] and *TTN/CCDC141*.[52] The leading variants at four of the SSS loci are missense.

KRT8 encodes K8, a cytoskeletal intermediate filament protein widely expressed, including in skeletal muscle and the heart.[55] Historically, keratins have been described as epithelial-specific intermediate filaments[70] and mutations affecting keratin function have almost exclusively been associated with diseases of the skin and other epithelial tissues.[71,72] The association of p.Gly62Cys in *KRT8* with SSS described here supports the notion of a role for K8 in the human heart, as previously suggested by animal studies.[73–76] Experiments have revealed loss-of-function effects of p.Gly62Cys, that is located in the head domain of K8 (Supplementary material online, *Figure S3*).[77,78] Glycine at position 62 is a conserved amino acid (GERP[79] score 1.73) and the variant introduces cysteine into a protein otherwise devoid of cysteine residues. This interrupts intermediate filament assembly *in vitro*[77] and prevents K8 from serving as a phosphate 'sponge' for stress-activated kinases that mediate apoptosis.[78] Thus, the variant could increase the risk of SSS either by affecting the structural or cardioprotective role of K8.[77,78]

In addition to p.Gly62Cys in *KRT8*, lead variants at two other SSS loci are missense variants in genes encoding structural components of the heart. *MYH6* encodes the alpha-myosin heavy chain (αMHC) and *TTN* encodes the giant protein titin, both of which are key components of the sarcomere.[80,81] Since the identification of *MYH6* in

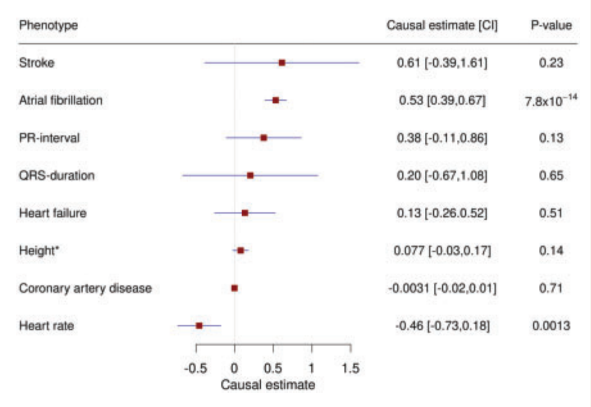

Figure 3 Forest plot showing causal effect estimates from a Mendelian randomization analysis of putative risk factors on SSS. We regressed published effects of SNPs on the respective exposure phenotype against their SSS effects in deCODE, CHB-CVS/DBDS, and the UK Biobank. The causal estimates are the slopes from the regression lines where a one unit change in the exposure phenotypes equals a one standard deviation change for quantitative traits and an odds ratio of 2.7 for binary exposure phenotypes. The forest plot shows the causal estimates, 95% confidence intervals, and corresponding *P*-values from the Mendelian randomization analysis. *For height, the result from a multivariate analysis accounting for AF effects is shown.

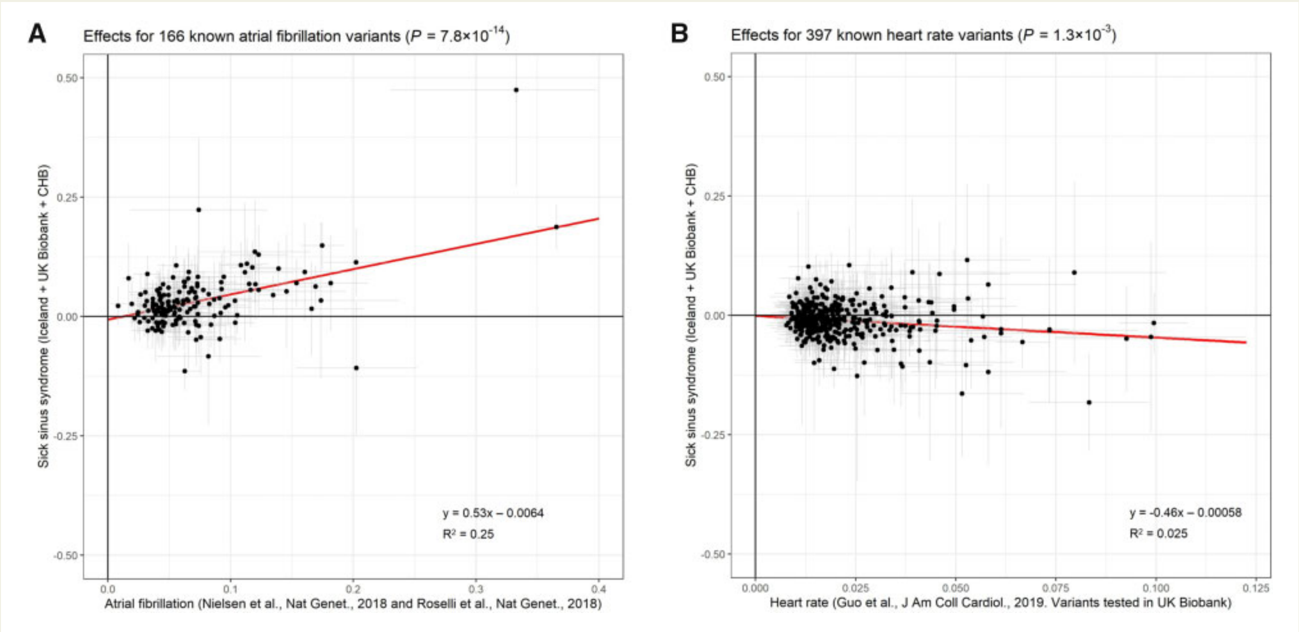

Figure 4 Visualization of significant associations from Mendelian randomization analysis. Effects of published variants on two phenotypes plotted against their effects on SSS in deCODE, CHB-CVS/DBDS, and the UK Biobank (*y*-axes, $N = 6189$). The *x*-axes depict (*A*) published AF effects[41,42] and (*B*) heart rate effects in UK Biobank.[43] The equations for the regression lines are shown and the coefficients of determination (R^2).

the first GWAS of SSS,[16] structural components of cardiomyocytes have increasingly been implicated in atrioventricular conduction and arrhythmias, in particular AF.[23,41,82,83] However, the variants at *KRT8, MYH6* and *TTN* do not mediate their risk through AF because they either do not associate with AF (*KRT8* and *TTN*) or have a stronger effect on SSS risk (*MYH6*).

K8, αMHC, and titin have a common role in cardiac adaptive responses to stress which may be of relevance to their association with SSS. αMHC allows greater economy in force generation than the homologous beta chain and a shift in their relative expression plays a major role in regulating myocardial contractile activity.[84,85] Likewise, the isoform switch of titin alters ventricular filling[81,86] and K8 is upregulated under stress to maintain structural integrity.[76] The expression of all three genes is modified in human heart failure.[76,84,87] Thus, whether or not the SSS variants in *KRT8, MYH6* and *TTN* directly affect the SA node, it is possible that they could contribute to inadequate cardiac output and symptom development in SSS by interrupting adaptive increase in stroke volume.

The SSS variants at *PITX2* and *ZFHX3* point to genes encoding transcription factors.[88,89] They likely mediate their effects on SSS through AF since these have consistently been the strongest AF loci in GWAS.[42,50,51] Conversely, p.Val1073Ala in *SCN10A* has opposite effects on the two arrhythmias. The allele that increases the risk of SSS protects against AF.[53,61] It also prolongs the PR interval[53,54,61] and duration of the QRS complex.[52,54] *SCN10A* encodes the neuronal sodium channel isoform $\mathrm{Na_v}$1.8. A plausible mechanism behind the unique phenotypic effects of p.Val1073Ala involves $\mathrm{Na_v}$1.8s role in the way in which the autonomic nervous system affects the heart.[90–92] In support of this, animal studies have shown that blockade of $\mathrm{Na_v}$1.8 in intracardiac autonomic neurons in the ganglionated plexi (GP) suppresses AF inducibility.[90,91] The same applies to GP ablation in patients with AF.[93–95] However, GP ablation is controversial due to observed adverse events,[96–98] including development of SSS and pacemaker implantation.[99] The opposite effects of p.Val1073Ala on SSS and AF risk support concerns that GP ablation for AF treatment may cause SSS and links this adverse effect to $\mathrm{Na_v}$1.8 function specifically.

Our genetic analyses shed light on pathways contributing to the development of SSS and the role of risk factors. In particular, they provide insight into the intricate and debated relationship between SSS and AF.[22] Our Mendelian randomization analysis reveals a strong association between genetic predisposition for AF and risk of SSS. This is consistent with our previous report[23] and likely reflects causality. Pacing-induced AF has been shown to impair SA node function in dogs[100] and AF causes regional atrial substrate changes around the SA node in humans.[27] Pathobiological pathways common to AF and SSS, such as inflammation, interstitial atrial fibrosis, and alterations in intracellular Ca^{2+} dynamics, may also contribute to this trend.[22,26,101]

Importantly, our results also show that SSS does not only occur as a consequence of AF or pathways common to AF. This is evident in the case of SSS variants at *KRT8* and *TTN/CCDC141* that do not associate with the risk of AF in a large dataset. p.Gly62Cys in *KRT8* is the only SSS variant that does not associate with other arrhythmias, ECG traits, or cardiovascular diseases in our dataset. Thus, this variant in particular may point to a mechanism that is specific to SSS development. We observe a genome-wide significant association of p.Glu382Asp in *CCDC141* with third-degree AVB, the first one reported for complete heart block. Therefore, this locus points to a

Downloaded from https://academic.oup.com/eurheartj/advance-article/doi/10.1093/eurheartj/ehaa1108/6134552 by Medicinsk Bibliotek, Aalborg Sygehus SYD user on 11 March 2021

mechanism linking the functions of the AV and SA nodes and does not mediate the risk of SSS as a consequence of AF. The complexity of the relationship between SSS and AF is further evident by the opposite effects of the *SCN10A* locus on the two arrhythmias. Finally, since SSS variants do not consistently associate with AF, our data do not suggest a strong causal role for SSS in the development of AF.

Heart rate variants associate inversely with SSS, consistent with epidemiological observation,[17] potentially because bradycardia is an integral part of the SSS diagnosis. However, lower heart rate could also represent a direct marker of biological processes affecting SSS, such as fibrosis or altered autonomic neural input. Finally, lack of associations with powerful PGSs based on large datasets serves as convincing evidence against causality.[25] In particular, this applies to BMI, cholesterol, triglycerides, and T2D.

Several of our findings have direct clinical implications. In particular, the causal role of AF in SSS development emphasizes the need for heightened awareness of potential SSS among patients with AF, especially those with unspecific symptoms. Furthermore, the strong association of the SSS variant p.Glu382Asp in *CCDC141* with AVB encourages consideration of dual chamber pacemaker implantation in SSS patients carrying this variant. Lastly, the *SCN10A* locus points to SSS as a potential adverse effect of GP ablation therapy for AF.

The major strength of the study is the large SSS sample set and extensive phenotypic and genotypic data for the same datasets. Different proportions of comorbidities and drug use in SSS cases and controls could constitute confounding; however, the consistent associations of SSS variants with both SSS and pacemaker implantation across cohorts support their true effect on cardiac conduction. Furthermore, if a specific comorbidity would explain one of the SSS associations, this would be evident by a stronger effect on that phenotype. The strength of Mendelian randomization in determining causality includes less concern for confounding and reverse causation than in observational studies since sequence variants associated with the exposure (e.g. AF) are randomized during meiosis and this process is unaffected by the presence of the outcome (SSS) later in life.[24] For heart failure, a limitation of the Mendelian randomization analysis is that variants identified in GWAS are not ideal instruments because of their association with potential confounders (e.g. AF, CAD, and BMI).[47]

Conclusion

In this large genetic study, we found six SSS loci, some of which also associate with other arrhythmias and cardiac electrical function. One of the associations is with a missense variant in the intermediate filament gene *KRT8* that confers high risk of SSS among homozygous carriers. Mendelian randomization analysis suggests that AF and lower heart rate are directly involved in SSS development. PGS analysis provides convincing evidence against causality for BMI, cholesterol, triglycerides, and T2D. On the other hand, the data also show that SSS can result from perturbation of pathways unrelated to AF. In particular, p.Gly62Cys at *KRT8* does not associate with any other cardiovascular traits and points to a mechanism that is specific to SSS development.

See the editorial comment for this article 'The journey towards identification of actionable molecular pathways in calcific aortic valve stenosis', by S. Thériault et al., https://doi.org/10.1093/eurheartj/ehad134.

Abstract

Aims Although highly heritable, the genetic etiology of calcific aortic stenosis (AS) remains incompletely understood. The aim of this study was to discover novel genetic contributors to AS and to integrate functional, expression, and cross-phenotype data to identify mechanisms of AS.

Methods and results A genome-wide meta-analysis of 11.6 million variants in 10 cohorts involving 653 867 European ancestry participants (13 765 cases) was performed. Seventeen loci were associated with AS at $P \leq 5 \times 10^{-8}$, of which 15 replicated in an independent cohort of 90 828 participants (7111 cases), including *CELSR2–SORT1*, *NLRP6*, and *SMC2*. A genetic risk score comprised of the index variants was associated with AS [odds ratio (OR) per standard deviation, 1.31; 95% confidence interval (CI), 1.26–1.35; $P = 2.7 \times 10^{-51}$] and aortic valve calcium (OR per standard deviation, 1.22; 95% CI, 1.08–1.37; $P = 1.4 \times 10^{-3}$), after adjustment for known risk factors. A phenome-wide association study indicated multiple associations with coronary artery disease, apolipoprotein B, and triglycerides. Mendelian randomization supported a causal role for apolipoprotein B-containing lipoprotein particles in AS (OR per g/L of apolipoprotein B, 3.85; 95% CI, 2.90–5.12; $P = 2.1 \times 10^{-20}$) and replicated previous findings of causality for lipoprotein(a) (OR per natural logarithm, 1.20; 95% CI, 1.17–1.23; $P = 4.8 \times 10^{-73}$) and body mass index (OR per kg/m^2, 1.07; 95% CI, 1.05–1.9; $P = 1.9 \times 10^{-12}$). Colocalization analyses using the GTEx database identified a role for differential expression of the genes *LPA*, *SORT1*, *ACTR2*, *NOTCH4*, *IL6R*, and *FADS*.

Conclusion Dyslipidemia, inflammation, calcification, and adiposity play important roles in the etiology of AS, implicating novel treatments and prevention strategies.

Structured Graphical Abstract

Key Question

What genes and biological pathways play key roles in the aetiology of aortic stenosis (AS)?

Key Finding

Genetic variation that contributes to aortic stenosis was found to impact lipids, inflammation, calcification, and obesity.

Take Home Message

The identification of specific genes and pathways increases our understanding of the disease processes that result in aortic stenosis, and may eventually lead to the identification of high-risk patients and novel therapeutic approaches.

Genetic etiology of aortic stenosis. This study meta-analyzed 13 765 AS cases vs. 640 102 controls and confirmed 15 genetic loci associated with AS. Downstream analyses implicated additional candidate genes involved in dyslipidemia, inflammation, calcification, and adiposity. The Manhattan plot shows variants with $P \geq 1 \times 10^{-25}$, for improved visualization. Genetic loci in grey were previously identified, and those in gold are new discoveries. Abbreviations: AS, aortic stenosis; GWAS, genome-wide association study; LDL, low-density lipoprotein.

Keywords Aortic stenosis • Genome-wide association study • Mendelian randomization • Phenome-wide association study • Gene expression • Genetic risk score

Translational perspective

This large-scale genetic study of calcific aortic stenosis (AS) in 653 867 European ancestry participants (13 765 cases) identified 15 robustly replicated genetic loci, including *SORT1–CELSR2*, involved in lipid metabolism, and *NLRP6*, involved in the inflammatory response. We provided evidence in favor of a causal association for apolipoprotein B, lipoprotein(a), body mass index, and low-density lipoprotein cholesterol. A genetic risk score including all identified loci was associated with both AS and aortic valve calcium and improved the classification of AS when added to risk factors. The differential expression of several genes in relevant tissues highlights their role in the etiology of AS. Together, these findings provide candidates for therapeutic targeting and highlight the use of a genetic risk score to improve clinical risk assessment.

Introduction

Calcific aortic stenosis (AS) is the leading form of incident valvular heart disease in high-income populations.[1] In individuals over 75 years, the prevalence of AS is 10%–15% but is expected to more than double by 2040.[2] Although a replacement of the aortic valve is effective for severe AS cases,[3,4] there are no treatments to prevent progression to valve replacement. Furthermore, it remains unclear which patients are at high risk of a severe prognosis.

A genetic component contributes to the etiology of AS, as siblings of AS patients have more than four-fold the risk of AS.[5] Several families have also been identified with many affected members, including 1 extended family with 48 cases of severe AS.[6] Previous genome- and transcriptome-wide association efforts have identified seven genetic loci associated with AS,[7–11] including *LPA*[7] [which codes for the apolipoprotein(a) moiety of lipoprotein(a)], *IL6*[10] (which codes for interleukin-6), and the *FADS1/2* gene cluster[11] (which codes for desaturases involved in fatty acid biosynthesis). Additionally, Mendelian randomization studies supported a causal contribution of low-density lipoprotein cholesterol (LDL-C),[12] non-high-density lipoprotein cholesterol,[9] lipoprotein(a),[13] arachidonic acid[11], and body mass index (BMI)[14] to AS, suggesting susceptibility to AS is partially mediated by lipid metabolism and inflammation.

Identifying additional genetic loci for AS could provide novel targets for therapeutic intervention and improve risk stratification. Accordingly, we combined genome-wide association study (GWAS) results from 10 cohorts to identify novel loci. We conducted functional analyses for significant variants, examined their association with biomarkers and other diseases, assessed cross-ancestry transferability of variants, and developed an AS genetic risk score to assess its association with diagnosed AS. Finally, we investigated whether individual genes or gene sets were predicted to be differentially expressed in AS cases.

Methods

Cohorts and case definition

The cohorts included in the meta-analysis are listed in *Table 1*. A full description of the cohorts and their case definition for identifying AS is in the Supplementary material online.

Genome-wide meta-analysis for aortic stenosis

We performed centralized, cohort-specific quality control of genome-wide summary statistics for prevalent AS from 10 cohorts totaling 653 867 European ancestry participants (13 765 cases) (*Table 1*). With the exception of the Malmö Diet and Cancer Study, which excluded variants with >5% genotype missingness, minor allele frequency ≤1%, and Hardy–Weinberg equilibrium test $P \geq 1 \times 10^{-4}$, and deCODE, which excluded variants not found in the Haplotype Reference Consortium version r1.1 panel, quality control used unified criteria. For all cohorts, we included bi-allelic variants with non-ambiguous strands (i.e. no C/G or A/T allele pairs), imputation quality score ≥0.3, and minor allele frequency ≥0.001 and whose associations with AS had standard errors less than or equal to the median standard error plus five times the interquartile range, calculated from all summary statistics from each cohort. Using PLINK version 1.9, we performed inverse variance-weighted, fixed-effects meta-analysis for 11 591 806 variants with summary statistics that passed quality control and the allele frequency threshold in at least two cohorts. For independent ($r^2 \leq 0.01$) and genome-wide significant ($P \leq 5 \times 10^{-8}$) variants, i.e. index variants and variants in high linkage disequilibrium (LD) ($r^2 \geq 0.95$) in European ancestry individuals of the Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort or the 1000 Genomes Project Phase 3,[15] we used the University of California Santa Cruz[16] GRCh37 assembly for genomic location.

Among 90 828 participants (7111 AS cases) from the Copenhagen Hospital Biobank or the Danish Blood Donor Study, we evaluated replication of the association with AS for all index variants. Associations were modeled using logistic regression adjusted for age, sex, and 10 principal components, with a $P \leq 0.05$ considered as replication. For all index variants, we also performed inverse variance-weighted, fixed-effects meta-analysis of summary statistics from the discovery and replication cohorts. For additional cohort details, see the Supplementary material online.

Region, gene-based, and functional analysis of variants

We used Annotate Variation (ANNOVAR)[17] to extract predicted function and pathogenicity of variants, including scores generated by Combined Annotation Dependent Depletion (CADD),[18] Deleterious Annotation of genetic variants using Neural Networks (DANN),[19] Linear INSIGHT (LINSIGHT),[20] Eigen-Principal Component (EIGEN-PC),[21] and Functional Analysis Through Hidden Markov Models-Multiple Kernel Learning (FATHMM-MKL) non-coding.[22] From Genotype-Tissue Expression Project (GTEx) version 8,[23] we identified significant expression quantitative trait loci in the aorta, left ventricle, liver, and whole blood. To identify gene regions associated with AS, we employed the single-nucleotide polymorphism (SNP)-wise mean approach of Multi-marker Analysis of GenoMic Annotation (MAGMA)[24] to test for association. We employed MetaXcan[25] and coloc[26] to identify variants whose effects on AS may be mediated by gene expression. We also applied the Genotype Imputed Gene Set Enrichment Analysis (GIGSEA)[27] approach, to assess whether sets of genes with shared function or regulation demonstrate differential predicted expression. We examined gene sets defined by the Kyoto Encyclopedia of Genes and Genomes (KEGG),[28] genes in the same pathway; Gene Ontology (GO),[29] genes with related functions; Functional ANnoTation Of the Mammalian genome version 5 (FANTOM5),[30] genes with shared transcription factor binding sites; and miRBase,[31] genes with the same microRNA seed sequence in their 3' untranslated region.

Genetic risk scores

We constructed three separate genetic risk scores. The first two used PLINK version 2.0[32] with weights estimated from a meta-analysis excluding the UK Biobank: a GRS_{18}, using all 18 genome-wide significant index variants from the discovery analysis, as well as a GRS_{559} including the 559 variants at $P < 1 \times 10^{-4}$. We assessed the association of GRS_{18} and GRS_{559} with AS in 220 159 unrelated White British participants in the UK Biobank aged 55 years or older (3091 cases) (see Supplementary material online) using a logistic regression model adjusted for age[2] and sex and then further adjusted for diabetes, LDL-C, systolic blood pressure, smoking (ever/never), BMI, and coronary artery disease (CAD). The UK Biobank participants in these and subsequent analyses differed slightly from the discovery analysis as an updated version of the data became available. In addition, we performed a polygenic risk score (PRS) analysis with LDpred2[33] in 244 641 UK Biobank participants (3410 cases). We also assessed the association of all the risk scores with the presence of aortic valve calcium (AVC) in the Multi-Ethnic Study of Atherosclerosis (MESA), using logistic regression adjusted for age and sex and then fully adjusted for fasting glucose, LDL-C, systolic blood pressure, smoking (ever/never), BMI, and coronary artery calcium. The PLINK-derived risk scores used 17 and 550 variants as neither variants nor proxies were available for some SNPs in this dataset. For the GRS_{17} and GRS_{550} risk scores, 2440 unrelated European participants (381 cases of AVC >0) were analyzed. The PRS analysis with LDpred2 included 2205 unrelated European participants (355 cases with AVC >0) of MESA. The area under the receiver operating characteristic curve (AUC) for the null hypothesis of no risk score was compared to other models using DeLong's test for two correlated ROC curves from the pROC R package.

Cross-ancestry and cross-phenotype associations

In the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium, we extracted summary statistics[7] for the association of the index variants with prevalent AVC in an inverse variance-weighted fixed-effects meta-analysis of three independent cohorts totaling 6942 European participants (2245 cases), adjusting for age and sex. Variants that were not available were replaced with one in high LD ($r^2 \geq 0.8$) when available.

To examine the association of index variants with AS in other ancestries, we analyzed 1917 African American participants (86 cases) and 3482 Latin American participants (159 cases) of the GERA cohort, adjusted for age[2] and sex.

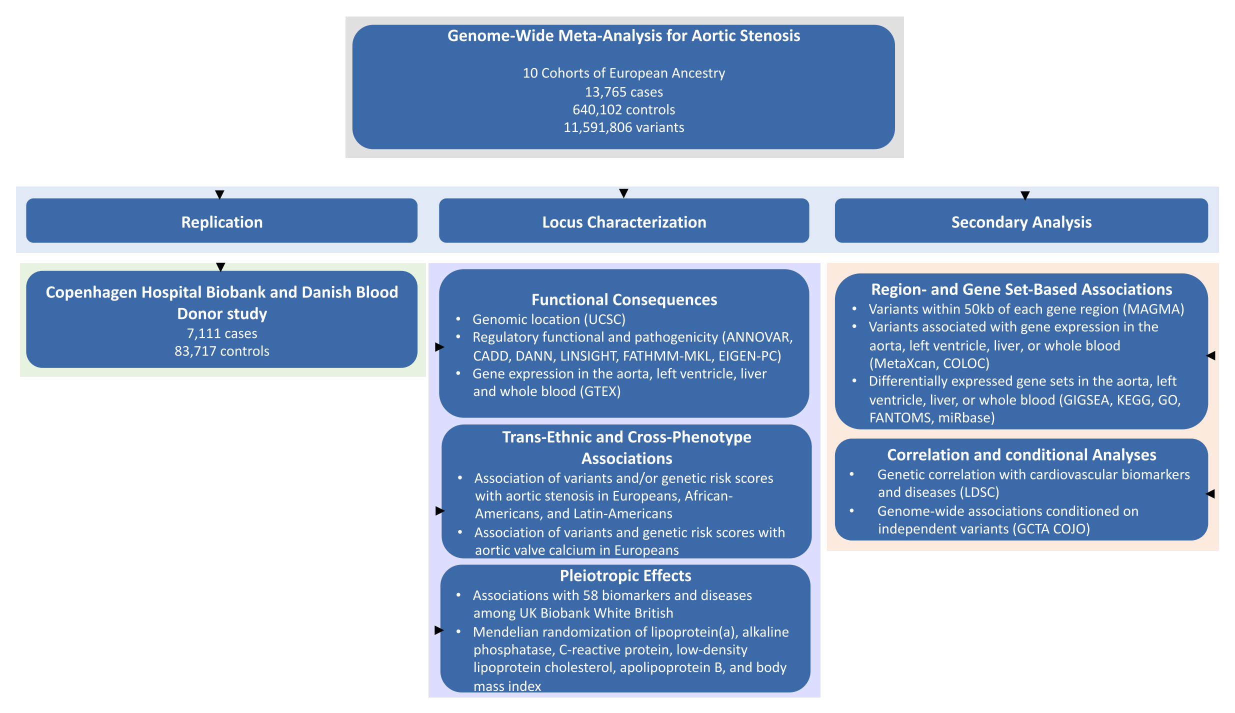
We performed a phenome-wide association study of the index variants with 58 diseases, serum biomarkers, and physiological measurements, among 257 231 unrelated White British UK Biobank participants aged 55 years or older. Disease cases were identified using hospital diagnosis codes, procedure codes, and causes of death. Levels of alkaline phosphatase, C-reactive protein, gamma-glutamyl transferase, lipoprotein(a), and triglycerides were natural logarithm transformed. Logistic and linear regression models were adjusted for age[2] and sex, except for breast cancer (analyzed only in women). A false discovery rate correction of 5% was applied across phenotypes for each variant tested.

For six traits associated with multiple variants in the phenome-wide association study, we performed two-sample Mendelian randomization to assess the causal contribution to AS. We performed a GWAS for each trait in unrelated UK Biobank White British participants (up to 383 533 participants). We constructed a genetic instrument for each biomarker using genome-wide significant variants ($331 \leq n \leq 702$) which were independent ($r^2 \leq 0.01$) with imputation quality ≥0.3 and minor allele frequency ≥0.001. We used the R package MendelianRandomization version 0.4.2[34] to estimate the inverse variance-weighted association with AS, using summary statistics from our discovery meta-analysis. The summary statistics for AS were generated with meta-analysis results that did not include UK Biobank so that instruments and outcomes were from non-overlapping cohorts. In secondary analyses, we also applied the contamination mixture, penalized weighted median, and Egger approaches.

Correlation and conditional analyses

We estimated the genetic correlation of AS with 157 cardiovascular biomarkers, risk factors, and diseases using the LD score regression method[35] as implemented on LD Hub.[36] We selected GWAS or meta-analyses which had been performed in European populations and applied a 5% false discovery rate correction.

To identify additional variants associated with AS, we used the conditional and joint analysis method[37] from the Genome-wide Complex Trait Analysis (GCTA) software[38] to re-estimate the summary statistics from our genome-wide meta-analysis conditioned upon the index variants. Variants not genome-wide significant in the original meta-analysis but which (i) became genome-wide significant in the conditional analysis and (ii) were independent ($r^2 \leq 0.01$) would be deemed to be novel associations.



Genome-Wide Meta-Analysis for Aortic Stenosis
10 Cohorts of European Ancestry
13,765 cases
640,102 controls
11,591,806 variants
Replication
Locus Characterization
Secondary Analysis
Copenhagen Hospital Biobank and Danish Blood Donor study
7,111 cases
83,717 controls
Functional Consequences
• Genomic location (UCSC)
• Regulatory functional and pathogenicity (ANNOVAR, CADD, DANN, LINSIGHT, FATHMM-MKL, EIGEN-PC)
• Gene expression in the aorta, left ventricle, liver and whole blood (GTEX)
Trans-Ethnic and Cross-Phenotype Associations
• Association of variants and/or genetic risk scores with aortic stenosis in Europeans, African-Americans, and Latin-Americans
• Association of variants and genetic risk scores with aortic valve calcium in Europeans
Pleiotropic Effects
• Associations with 58 biomarkers and diseases among UK Biobank White British
• Mendelian randomization of lipoprotein(a), alkaline phosphatase, C-reactive protein, low-density lipoprotein cholesterol, apolipoprotein B, and body mass index
Region- and Gene Set-Based Associations
• Variants within 50kb of each gene region (MAGMA)
• Variants associated with gene expression in the aorta, left ventricle, liver, or whole blood (MetaXcan, COLOC)
• Differentially expressed gene sets in the aorta, left ventricle, liver, or whole blood (GIGSEA, KEGG, GO, FANTOMS, miRbase)
Correlation and conditional Analyses
• Genetic correlation with cardiovascular biomarkers and diseases (LDSC)
• Genome-wide associations conditioned on independent variants (GCTA COJO)

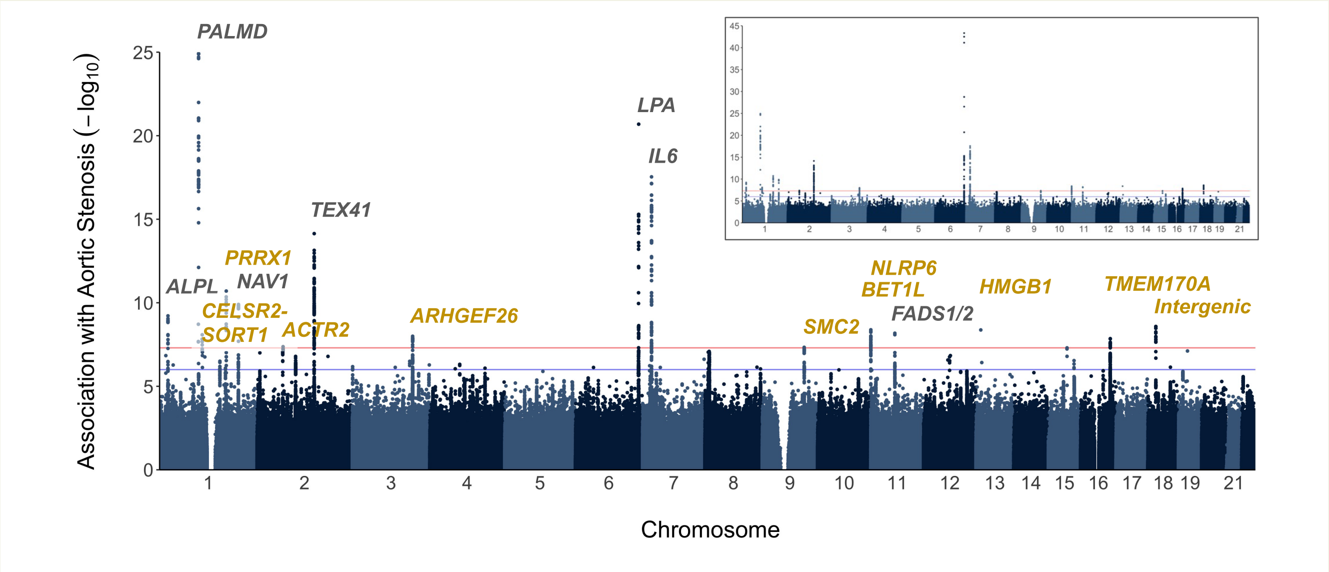

Figure 2 *P* for the association of 11 591 806 variants with aortic stenosis in the meta-analysis. The inset shows all associations, while the main plot shows variants with $P \geq 1 \times 10^{-25}$, for improved visualization. Genetic loci in grey were previously identified and those in gold are new discoveries.

Results

Genome-wide meta-analysis identifies 10 novel loci for aortic stenosis

We performed a genome-wide meta-analysis for AS using summary statistics from 10 European ancestry cohorts totaling 653 867 participants (13 765 cases) (*Table 1*). Estimates for each of 11 591 806 variants were combined in an inverse variance-weighted, fixed-effects model (see *Figure 1* for study design overview). We observed no evidence of strongly inflated test statistics in the meta-analysis (genomic inflation factor [λ] = 1.04 and LD score regression intercept = 1.020; Supplementary material online, *Figure S1*).

We identified 17 genetic loci containing one or more independent variants ($r^2 \leq 0.01$) which exceeded a genome-wide significance threshold ($P \leq 5 \times 10^{-8}$) for association with AS (*Figure 2*). We confirmed all 7 known loci and identified 10 loci not previously reported to be genome-wide significant. After pruning for variants in LD, we identified 18 independent variants ($r^2 \leq 0.01$) (see meta-analysis results in *Table 2* and forest plots in Supplementary material online, *Figure S2*). The association with AS of variants surrounding the index variants is provided in Supplementary material online, *Figure S3*).

Subsequently, we performed a replication study of the association for each of the 10 previously unreported loci with AS in 90 828 individuals (7111 AS cases) from the Danish Blood Donor Study and Copenhagen Hospital Biobank, and variants at 8 of these 10 loci were nominally associated with AS with concordant direction of effect ($P \leq 0.05$) (*Table 2*). The two least common variants, *BET1L* rs73386631 and *HMGB1* rs181753401, were not associated with AS in this cohort, and meta-analysis of the discovery and replication cohorts did not achieve genome-wide significance (*Table 2*).

When we re-estimated the association of variants with AS in the genome-wide meta-analysis, conditioned upon the 18 index variants, the *PLG* variant rs191108153 became genome-wide significant [odds ratio (OR) per T allele, 1.57; 95% CI, 1.34–1.83; $P = 9.6 \times 10^{-9}$]. Given the proximity of this variant to *LPA*, we tested the association of this variant with AS conditioned on genetically predicted levels of lipoprotein(a) and observed substantial attenuation (OR per T allele, 1.20; 95% CI, 1.03–1.40; $P = 0.019$).

We examined publicly available databases for functional effects of the index variants and their proxies in high LD ($r^2 \geq 0.95$) (see Supplementary material online, *Tables S1* and *S2*). *ARGHEF26* rs6794263 was in high LD ($r^2 = 0.99$)[39] with the missense variant rs13096373 (p.Phe203Ser). This substitution was predicted by the CADD software[40] to be in the 5% most deleterious substitutions (scaled C-score = 14.5). Variants in the *CELSR2–SORT1*, *PRRX1*, *NLRP6*, *PALMD*, and *IL6* loci and the intergenic region at 18q11.2 had high CADD scores, and variants at the *ACTR2* and *NLRP6* loci were in the 5% most pathogenic variants according to DANN[19] (ranked score ≥ 0.95). Variants at the *CELSR2–SORT1*, *PRRX1 PALMD*, *IL6*, *FADS1/2*, and 18q11.2 regions were classified as deleterious using the FATHMM-MKL non-coding approach ($P \geq 0.5$).[22]

Identified variants are also associated with aortic valve calcium

From a previous meta-analysis for AVC involving 6942 European participants from three cohorts in the CHARGE consortium (2245 participants with AVC >0),[7] we identified fixed-effects associations with prevalent AVC for the index variants. For unavailable variants, a proxy in high LD ($r^2 \geq 0.8$) was used, but no proxies were found for *LPA* rs140570886 and *HMGB1* rs181753401. Five variants were nominally associated with the presence of AVC in the same direction of effect as for AS ($P \leq 0.05$): *PRRX1* rs61817383 (OR per minor allele, 1.10; 95% CI, 1.01–1.21; $P = 0.035$), *ACTR2* rs62139062 (OR per minor allele, 1.11; 95% CI, 1.01–1.21; $P = 0.029$), *LPA* rs10455872 (OR per minor allele, 2.05; 95% CI, 1.63 to 2.57; $P = 9.0 \times 10^{-10}$), *NLRP6* rs17156153 (OR per minor allele, 1.17; 95% CI, 1.02–1.35; $P = 0.028$),

and *FADS1/2* rs174533 (OR per minor allele, 0.91; 95% CI, 0.83–0.99; $P = 0.024$) (see Supplementary material online, *Table S3*).

Genetic risk scores are associated with aortic stenosis and aortic valve calcium

The prevalence of AS increased across GRS_{18} risk score tertiles, ranging from 0.97% in the lowest tertile to 1.92% in the highest tertile (see Supplementary material online, *Figure S4*). Each 1 standard deviation (SD) higher GRS_{18} was associated with 37% higher odds of AS (OR per SD, 1.37; 95% CI, 1.32–1.41; $P = 3.0 \times 10^{-72}$) with an AUC of 0.697, when adjusted for age[2] and sex, with a similar OR after additional adjustment for diabetes, LDL-C, systolic blood pressure, smoking, BMI, and CAD (OR per SD, 1.31; 95% CI, 1.26–1.35; $P = 2.6 \times 10^{-51}$) (see Supplementary material online, *Table S4*). The AUC for this full model was 0.824, the addition of the genetic risk score modestly improving the AUC compared to a model restricted to non-genetic cardiovascular risk factors only (AUC = 0.818; $P_{\text{AUC difference}} = 5.9 \times 10^{-6}$). The GRS_{559} demonstrated stronger effect sizes and higher discrimination in the fully adjusted model (OR 1.53 per 1-SD GRS559, 95% CI 1.48–1.58; $P = 1.54 \times 10^{-141}$; AUC = 0.829; $P_{\text{AUC difference}} = 3.2 \times 10^{-9}$). In an additional sensitivity analysis, we dropped the six *LPA* region SNPs from the GRS_{559}, and this resulted in an OR of 1.50 per 1-SD for AS (CI 1.45–1.55; $P = 7.21 \times 10^{-130}$). Using the LDpred2 approach, we observed similar results with an OR of 1.45 per 1-SD (95% CI 1.41, 1.50; $P = 7.44 \times 10^{-122}$) and an AUC of 0.706 when adjusting only for age[2] and sex. In the model also adjusting for cardiovascular risk factors, we observed an OR of 1.40 (95% CI 1.36, 1.45; $P = 1.19 \times 10^{-84}$) and an AUC of 0.827 (see Supplementary material online, *Table S4*).

When we applied the GRS_{17} to MESA, the prevalence of AVC was 15.2%, 13.9%, and 17.7% in the first, second, and third tertiles, respectively (see Supplementary material online, *Figure S4*). After adjustment for age and sex, each 1 SD higher genetic risk score was associated with 22% higher odds of AVC (OR per SD, 1.22; 95% CI, 1.08–1.37; $P = 1.44 \times 10^{-3}$; AUC = 0.796), and this association persisted after additional adjustment for fasting glucose, LDL-C, systolic blood pressure, smoking, BMI, and coronary artery calcium (OR per SD, 1.23; 95% CI, 1.09–1.39; $P = 1.10 \times 10^{-3}$; AUC = 0.815). The GRS_{550} demonstrated weaker effects and worse discrimination with AVC when adjusted for age and sex (OR 1.15, 95% CI 1.02–1.29; $P = 0.022$; AUC = 0.794) as well as in the fully adjusted model (OR 1.15, 95% CI 1.02–1.30; $P = 0.023$; AUC = 0.814). Without the six *LPA* region SNPs, the OR was 1.11 per 1-SD for AVC (CI 0.98–1.25; $P = 0.093$). However, we observed stronger effects and better discrimination with LDpred2, an OR of 1.27 (1.12, 1.44; $P = 1.34 \times 10^{-9}$) and an AUC of 0.799 when adjusted for age and sex. In the fully adjusted model, we observed an OR of 1.32 (1.16, 1.50; $P = 2.24 \times 10^{-5}$) and an AUC of 0.823 (see Supplementary material online, *Table S4*).

A subset of the identified variants replicates in African and Latin Americans

When we examined the index variants among 1917 African American participants (86 cases) and 3482 Latin American participants (159 cases) from the GERA cohort, we observed replication ($P \leq 0.05$ for AS with concordant direction of effects) for *CELSR2–SORT1* rs12740374 in both ancestries, for *ALPL* rs6696066 and *NLRP6* rs17156153 in Latin Americans, and for *LPA* rs10455872 in African Americans (see Supplementary material online, *Table S5*).

Region-based analysis identifies additional associations with aortic stenosis

For each of 18 539 protein-coding genes, we used MAGMA[24] to examine the joint contribution of all variants in a gene region. We tested the mean association with AS of variants within 50 kb of each gene, correcting for LD between variants. We identified 95 regions associated with AS after Bonferroni correction (see Supplementary material online, *Table S6*), including regions spanning 11 of the 17 loci identified with single variant analysis (*ALPL*, *CELSR2*, *PRRX1*, *NAV1*, *ARHGEF26*, *LPA*, *IL6*, *BET1L*, *NLRP6*, *FADS1/2*, and *TMEM170A*). The *TMEM170A* gene region had a level of significance similar to an overlapping region defined by CFDP1 ($P = 2.9 \times 10^{-10}$ for *CFDP1* vs. $P = 4.5 \times 10^{-10}$ for *TMEM170A*). The three most significant regions not identified in the single variant-based approaches were *LDLR* ($P = 2.3 \times 10^{-10}$), *AGO2* ($P = 5.9 \times 10^{-10}$), and *XKR6* ($P = 9.8 \times 10^{-10}$). Although this approach did not account for LD between regions, these three regions were >100 Mb away from another association.

Expression-based analyses

We used MetaXcan[25] to analyze gene expression and expression quantitative trait loci (eQTL) extracted from GTEx project data.[23] We examined four tissues which may be involved in the AS disease process: aorta, left ventricle, liver, and whole blood. With a false discovery rate of 5%, we identified 42 genes with predicted expression that differed between cases and controls (see Supplementary material online, *Figure S5*). Increased *LPA* expression in the liver was predicted for AS cases (Z score = 5.25; $P = 1.5 \times 10^{-7}$). Expression of *IL6R* was inferred to be increased in the blood of cases (Z score = 4.66; $P = 3.1 \times 10^{-6}$). *NOTCH4* mRNA in the aorta was predicted to be decreased in cases (Z score = −4.07; $P = 4.7 \times 10^{-5}$). In contrast to these single tissue effects, inferred *RPS23* expression was lower in the blood, left ventricle, and aorta in AS cases ($P \leq 3.3 \times 10^{-5}$). The most significant, predicted differential expression was decreased *ZEB2* expression in the aorta of individuals with AS (Z score = −7.14; $P = 9.2 \times 10^{-13}$). Additional GIGSEA[27] were performed to infer the differential expression of genes (see Supplementary material online, *Table S7*).

As identified in GTEx,[23] the index variants at the *ACTR2* and *BET1L* loci were in high LD ($r^2 \geq 0.98$) with the most significant eQTL for their respective genes in the aorta. The index variant at the *ARHGEF26* locus was in high LD ($r^2 = 0.96$) with the most significant eQTL for *ARHGEF26* in the left ventricle. In addition, rs55909255 was associated with the expression of *SMC2* in the left ventricle, and rs140570886 was associated with the expression of *LPA* in the liver. Index variants and proxies at the *CELSR2–SORT1*, *IL6*, and *FADS1/2* loci were all eQTL for multiple genes in three to four tissues (see Supplementary material online, *Table S2*). Notably, the index variant at the *CELSR2–SORT1* locus was the most significant hepatic eQTL for *CELSR2* and *SORT1*, and the index variant at the *FADS1/2* locus was in high LD ($r^2 \geq 0.96$) with the most significant eQTL for *FADS1* in the aorta and liver. Neither the index variant at the *IL6* locus nor any variants in high LD ($r^2 \geq 0.95$) were associated with *IL6* expression in the tissues examined. However, the index variant was in high LD with the most significant eQTL for IL6 antisense RNA 1 (*IL6-AS1*) in the blood ($r^2 = 0.96$) (see Supplementary material online, *Table S2*). Several of these results were confirmed by additional colocalization analyses using MetaXcan and coloc (see Supplementary material online, *Figure S5*, and Supplementary material online, *Table S8*). Notably,

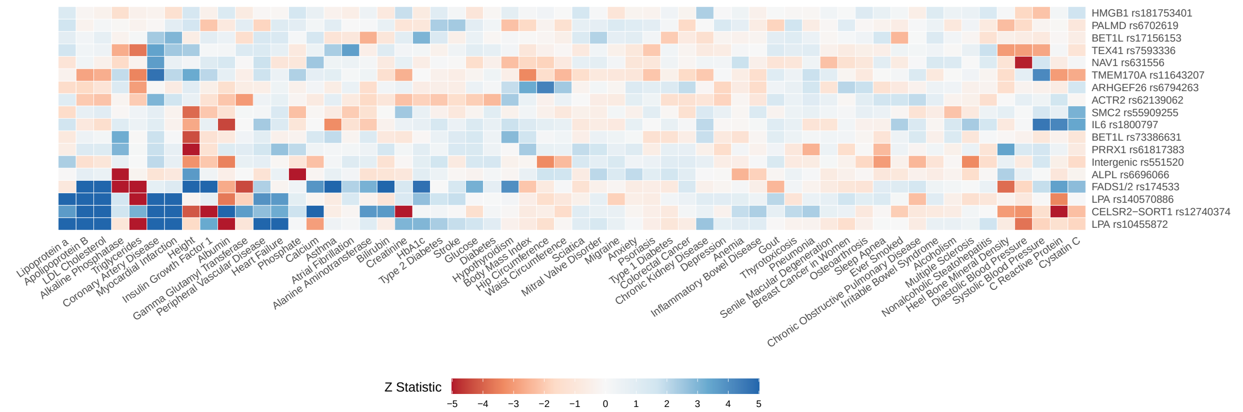

Figure 3 Association of aortic stenosis variants with biomarkers, physiological measurements, and diseases. Variants were ordered to reflect similarity in their associations with traits and vice versa. The strength and direction of associations are represented by cells of different colors, with blue cells indicating positive effects on the odds of aortic stenosis and red cells indicating inverse associations. For ease of visualization, Z statistics >5 or less than −5 were rounded to 5 and −5, respectively.

we identified high posterior probabilities for colocalization for SORT1 expression in the liver for rs6702619, as well as ACTR2 expression in the aorta for rs7556894 and FADS1 in whole blood and left ventricle for rs174535.

AS is genetically correlated with adiposity

Using LD score regression[35] as implemented on LD Hub,[36] we computed the genetic correlation of AS with 157 traits related to cardiovascular risk factors, metabolites, and immunological diseases using GWAS summary statistics. With a false discovery rate of 5%, we observed 32 (18.5%) traits that were genetically correlated with AS, most of which involved adiposity, glycemia, or lipids (see Supplementary material online, *Table S9*). Measures of adiposity were positively correlated with AS and represented seven of the 10 most significant correlations. The only inverse correlations were with high-density lipoprotein particles. The total lipid content of chylomicrons and large very low-density lipoprotein particles shared the highest absolute genetic correlation with AS (r_g, 0.31; 95% CI, 0.13 to 0.48; $P = 6.0 \times 10^{-4}$).

Pleiotropic effects of variants associated with aortic stenosis

We assessed the association of the index variants with 58 biomarkers, physiological measurements, and diseases among 257 231 UK Biobank White British participants. Traits were selected to reflect cardiovascular, cerebrovascular, immune, hepatic, and adiposity phenotypes. We observed 98 associations with false discovery rate-adjusted $P \leq 0.05$ and the five most significant associations involved apolipoprotein B, lipoprotein(a), LDL-C, or triglycerides (see Supplementary material online, *Table S10*). The traits with the greatest number of associations were height (eight variants); CAD, albumin, and triglycerides (six variants each); C-reactive protein and apolipoprotein B (five variants each); and heel bone mineral density, diastolic blood pressure, and LDL-C cholesterol (four variants each) (*Figure 3*; Supplementary material online, *Table S10*).

Blood-based biomarkers are causal contributors to aortic stenosis

We performed Mendelian randomization for six traits associated with several variants in the phenome-wide association study. We constructed genetic instruments using summary statistics from GWAS performed on UK Biobank (White British) and assessed the association of these instruments with AS. Using the IVW method, genetically elevated levels of apolipoprotein B, lipoprotein(a), LDL-C, and BMI were associated with increased odds of AS [OR per g/L of apolipoprotein B, 3.85; 95% CI, 2.90–5.12; $P = 2.1 \times 10^{-20}$; OR per natural logarithm of lipoprotein(a), 1.20; 95% CI, 1.17–1.23; $P = 3.0 \times 10^{-53}$; OR per mmol/L of LDL-C, 1.57; 95% CI, 1.44–1.71; $P = 1.5 \times 10^{-25}$; OR per kg/m^2 of BMI, 1.07; 95% CI, 1.05, 1.09; $P = 1.9 \times 10^{-12}$, respectively], with no evidence of pleiotropy (all Egger intercepts $P > 0.05$) (see Supplementary material online, *Table S11*). The associations between AS and higher genetically predicted levels of both C-reactive protein and alkaline phosphatase were pleiotropic (Egger intercept P-values of 0.024 and 0.003), and MR results were not consistent across methods limiting causal inference (see Supplementary material online, *Table S11*).

Discussion

In this genome-wide meta-analysis combining summary statistics from 10 cohorts of European ancestry, we confirmed association for seven previously identified loci and identified 10 loci not previously reported to be genome-wide significant for AS. For newly discovered variants, we observed modest changes in AS odds (9%–55% increased odds per risk allele). In independent replication, 8 of the 10 previously unreported variants were associated with AS, with the exception of *BET1L* rs73386631 and *HMGB1* rs181753401 which had low allele frequencies. Our work brings the total number of loci robustly associated with AS to 15. Several of these variants were associated with AS in other ancestries, and a risk score composed of all identified variants was a predictor of AS independent of other risk factors. Further analysis using region- and gene-based methods identified additional gene regions associated with AS, including *LDLR* and *NOTCH4*, as well as

Downloaded from https://academic.oup.com/eurheartj/article/44/21/1927/7112365 by guest on 15 October 2025

differential expression of co-regulated groups of genes. Finally, Mendelian randomization supported a causal contribution of lipoprotein(a), apolipoprotein B, LDL-C, and BMI to AS.

Our findings support four key etiological mechanisms for AS: calcification, lipid metabolism, adiposity, and inflammation (*Structured Graphical Abstract*). The variants at the *PRRX1*, *ACTR2*, *LPA*, *NLRP6*, and *FADS1/2* loci were also associated with aortic valve calcification assessed by computed tomography. We observed associations of the index variants at the *CELSR2–SORT1*, *PRRX1*, *TEX41*, and *FADS1/2* loci with heel bone mineral density, suggesting systemic effects on calcification. The paired-related homeobox protein 1, the product of the locus *PRRX1*, is a transcription factor required for osteoblast differentiation by TNF-α[41] and is an inducer of the epithelial–mesenchymal transition,[42] a key process in early calcification. Interestingly, zinc finger e-box binding homeobox 2, coded by *ZEB2*, is a repressor of this process.[43] Predicted *ZEB2* expression in the aorta was the most significant differentially expressed gene. Consistent with a potential role in calcification, earlier work demonstrated that *TEX41* variants may be associated with AS through long-range chromatin interactions with the *ZEB2* promoter region, including in the aorta[9] implicating *TEX41*, *ZEB2*, and *PRRX1* in inducing early calcification and subsequent valve stenosis.

Located in the 3' untranslated region of *CELSR2*, rs12740374 affects expression of *SORT1*,[44] which has been reported to decrease hepatic excretion of apolipoprotein B and increase catabolism of LDL-C.[45] Studies have reported the association of lower LDL-C[46,47] and lower odds of CAD,[48,49] and in a study involving two cohorts participating in the current study, a variant in perfect LD with rs12740374 was associated with AS after Bonferroni correction ($P = 3.4 \times 10^{-4}$).[9] The present analysis identified genome-wide significance in the association of the *CELSR2–SORT1* variant with AS. Consistent with its effects on LDL-C and apolipoprotein B, the minor allele conferred a reduction in the odds of AS. Additional evidence that lipid metabolism is a causal mechanism for AS was provided by Mendelian randomization, which confirmed the role of LDL-C[12] and identified a contribution of apolipoprotein B, which extends this association to all apolipoprotein B-containing lipoprotein particles. The findings were consistent with work demonstrating an association of a non-high-density lipoprotein cholesterol genetic risk score with AS.[9] In addition to these lipoprotein-mediated effects, sortilin, coded by *SORT1*, is a regulator of vascular calcification and is associated with increased aortic calcification in mice.[50] Furthermore, sortilin expression is associated with increased expression of *ALPL*,[50] a known AS locus replicated in this study.

Both overall and abdominal obesity have been previously associated with AS,[51] and a Mendelian randomization study provided support for the causality of BMI.[14] Our Mendelian randomization analyses replicate and extend these findings by observing genetic correlations between AS and multiple measures of adiposity, including BMI, waist and hip circumferences, and obesity. However, only one of our genome-wide significant variants, *ARHGEF26* rs6794263, which was in high LD with the missense variant rs13096373 (p.Phe203Ser), was associated with BMI and hip circumference in our phenome-wide analysis. Another missense variant rs12493885 (p.Val29Leu) in *ARHGEF26* was previously associated with CAD,[52] mediated by a gain of function for ARHGEF26 that may lead to increased transendothelial migration, greater adhesion of leukocytes, and proliferation of vascular smooth muscle cells.[52] However, this variant was independent of *ARHGEF26* rs6794263 ($r^2 = 0.018$)[39] and was not associated with AS in our meta-analysis (OR per T allele, 1.02; 95% CI, 0.98–1.06; $P = 0.44$ for rs1713812, which is in perfect LD with rs12493885[39]). Conversely, the allele of rs6794263 that confers a lower odds of AS has also been associated with lower odds of CAD, but not at genome-wide significance (OR per C allele, 0.96; 95% CI, 0.92–1.00; $P = 0.037$).[53] The presence of two independent, missense mutations in *ARHGEF26* with discordant effects on AS and CAD suggests pleiotropic effects of this locus.

The accumulation of inflammatory cells in the aortic valve is associated with remodeling and fibrosis,[54] highlighting the role for inflammation in disease progression. We confirmed that the *FADS1/2* locus was associated with AS.[11] Both *FADS1* and *FADS2* encode key enzymes in the conversion of dietary *n*-6 fatty acids to arachidonic acid, a precursor of pro-inflammatory leukotrienes and prostaglandins.[55] In addition, we also identified a novel variant at the locus for NLRP6, which assembles an inflammasome that plays a role in immunity to bacterial infection as well as proinflammatory responses to other stimuli, including fatty acids.[56,57] We replicated that the association previously reported between an *IL6* variant and AS[10] and the *IL6* variant rs2069832 ($r^2 = 0.95$ with our index variant) colocalizes with *IL6-AS1* expression.[10] Notably, the risk-increasing alleles are associated with increased expression of both *IL6* and *IL6-AS1* in fibroblasts in GTEx.[23] Our analyses therefore indicate a pro-inflammatory association with AS in the *IL6* region but also higher predicted *IL6R* expression in the blood cells of AS cases. Thus, several orthogonal signals support the association of pro-inflammatory pathways with AS.

The present study represents the largest genome-wide meta-analysis of AS, a common condition with no available medical treatment, and included 653 867 participants (13 765 cases) in which we applied variant-, gene-, and gene set-based analyses to identify additional risk loci and disease mechanisms. Our work highlights novel mechanisms and pathways which may have important clinical and future research implications. First, our analyses point to several possible therapeutic interventions using both lifestyle and novel drugs. Our findings of lipoproteins and adiposity as key drivers of aortic stenosis suggest that maintenance of healthy lifestyle and adherence to lipid-lowering recommendations may reduce the incidence of aortic stenosis. Furthermore, lipoprotein(a)-lowering therapies currently in development[58,59] may provide a new avenue for prevention of disease progression. Whether novel hypoglycemics, which also lead to marked weight loss and metabolic improvements,[60] and anti-inflammatory agents (e.g. that inhibit IL-6 signaling[61]) could reduce AS requires randomized trials. Finally, our observation of a robust association between a genetic risk score and AS may allow identification of patients at risk for rapid disease progression in clinical practice, who may require echocardiographic follow-up, as well as permit targeted enrolment of such at-risk patients in future randomized trials.

Despite the strengths of the study, there are several limitations. Since our discovery cohorts were of European ancestry, the transferability of our results to other ancestries may be limited.[62–64] Although we attempted cross-ancestry replication of genome-wide significant variants, the observed limited reproducibility may be due to the low numbers of African and Latin American participants. Future studies should focus on non-Europeans. Our analyses also made exclusive use of bioinformatic methods to identify genetic loci. These results require confirmation using complementary approaches. Lastly, cases were selected using various criteria (international classification of diseases (ICD) codes, surgical AVR, etc.) and not solely by echocardiography. Therefore we could not entirely exclude bicuspid aortic valves; however, these likely represent a small proportion of the cases.

In conclusion, our results identify novel genetic contributors to AS and identify specific contributions to disease etiology that are characterized by the effects of calcification, altered lipid metabolism, adiposity, and inflammation. An AS genetic risk score was an independent predictor of both clinical and subclinical disease, providing additional discrimination when added to clinical risk factors. Established and novel

Downloaded from https://academic.oup.com/eurheartj/article/44/21/1927/7112365 by guest on 15 October 2025

genetic loci warrant investigation as potential therapeutic targets to prevent the initiation of aortic calcification and progression to stenosis.

A full list of participating MESA investigators and institutions can be found at http://www.mesa-nhlbi.org. Multi-Ethnic Study of Atherosclerosis and the MESA SHARe project are conducted and supported by the National Heart, Lung, and Blood Institute (NHLBI) in collaboration with MESA investigators. Support for MESA is provided by contracts 75N92020D00001, HHSN268201500003I, N01-HC-95159, 75N92020D00005, N01-HC-95160, 75N92020D00002, N01-HC-95161, 75N92020D00003, N01-HC-95162, 75N92020D00006, N01-HC-95163, 75N92020D00004, N01-HC-95164, 75N92020D00007, N01-HC-95165, N01-HC-95166, N01-HC-95167, N01-HC-95168, N01-HC-95169, UL1-TR-000040, UL1-TR-001079, UL1-TR-001420. Funding for SHARe genotyping was provided by NHLBI Contract N02-HL-64278. Genotyping was performed at Affymetrix (Santa Clara, California, USA) and the Broad Institute of Harvard and MIT (Boston,

Massachusetts, USA) using the Affymetrix Genome-Wide Human SNP Array 6.0. Also supported in part by the National Center for Advancing Translational Sciences, CTSI grant UL1TR001881, and the National Institute of Diabetes and Digestive and Kidney Disease Diabetes Research Center (DRC) grant DK063491 to the Southern California Diabetes Endocrinology Research Center. This research was supported by R01 HL071739. Infrastructure for the CHARGE consortium is supported in part by the NHLBI grant R01HL105756 and also supported in part by National Institute of Health contract R01HL146860. Vanderbilt University Medical Center's BioVU projects are supported by numerous sources: institutional funding, private agencies, and federal grants. These include the National Institutes of Health Grant S10RR025141; Clinical and Translational Science Award grants UL1TR002243, UL1TR000445, and UL1RR024975. Genomic data are also supported by investigator-led projects that include U01HG004798, R01NS032830, RC2GM092618, P50GM115305, U01HG006378, U19HL065962, and R01HD07471. This work was supported by an ANR & FRM grant [13-BSV6-0011 and DCV20070409278] to Jean-Jacques Schott, by a Fédération Française de Cardiologie, a Fondation Coeur et Recherche and an Inserm Translational Research grant to Thierry Le Tourneau. Romain Capoulade is supported by a 'Connect Talent' research chair from Région Pays de la Loire. Cohort PREGI set up was supported by the French Regional Council of Pays-de-la-Loire (VaCaRMe program). We thank Marie Marrec and Guénola Coste for their contribution to clinical data collection and the Genomics and Bioinformatics Core Facility of Nantes (GenoBiRD, Biogenouest) for its technical support. The D.E.S.I.R. study (providing a set of controls) has been supported by INSERM contracts with CNAMTS, Lilly, Novartis Pharma, and Sanofi-Aventis; by INSERM (Réseaux en Santé Publique, Interactions entre les déterminants de la santé), Cohortes Santé TGIR, the Association Diabète Risque Vasculaire, the Fédération Française de Cardiologie, La Fondation de France, ALFEDIAM, Société francophone du diabète, ONIVINS, Abbott, Ardix Medical, Bayer Diagnostics, Becton Dickinson, Cardionics, Merck Santé, Novo Nordisk, Pierre Fabre, Roche, and Topcon. The D.E.S.I.R. Study Group. INSERM U1018: B. Balkau, P. Ducimetière, E. Eschwège; INSERM U367: F. Alhenc-Gelas; CHU D'Angers: A. Girault; Bichat Hospital: F. Fumeron, M. Marre, R Roussel; CHU de Rennes: F. Bonnet; CNRS UMR8090, Lille: A. Bonnefond, P. Froguel; Univ Paris Descartes, UMR1153, Paris: F.Rancière Centres d'Examens de Santé: Alençon, Angers, Blois, Caen, Chateauroux, Chartres, Cholet, Le Mans, Orléans, Tours; Institute de Recherche Médecine Générale: J. Cogneau; General practitioners of the Region; Institute inter-Regional pour la Santé: C. Born, E. Caces, M. Cailleau, O Lantieri, J.G. Moreau, F. Rakotozafy, J. Tichet, S. Vol. We would like to specially thank the team of the Centre d'Investigation Clinique (Xavier Duval), the Centre de Ressources Biologiques (Sarah Tubiana), Christophe Aucan from the Assistance Publique—Hôpitaux de Paris, Département de la Recherche Clinique et du Développement (DRCD) and Estelle Marcault from the Unité de Recherche Clinique Paris Nord for their help and support during all these years. The COFRASA (clinicalTrial.gov number NCT 00338676) and GENERAC (clinicalTrial.gov number NCT00647088) studies are supported by grants from the Assistance Publique—Hôpitaux de Paris (PHRC National 2005 and 2010, and PHRC regional 2007). The Copenhagen Hospital Biobank and The Danish Blood Donor Study were supported by the Novo Nordisk Foundation (grant numbers NNF14CC0001 and NNF17OC0027594). This work was further supported by The Innovation Fund Denmark (PM Heart) Nord-Forsk (project no. 90580) and the Capital Regions Research Council (No. A5920). None of the funding sources were involved in the collection, analysis, and interpretation of data, nor the writing of this paper or the decision to submit the paper for publication.

Abstract

Leishmania has a plastic genome, and drug pressure can select for gene copy number variation (CNV). CNVs can apply either to whole chromosomes, leading to aneuploidy, or to specific genomic regions. For the latter, the amplification of chromosomal regions occurs at the level of homologous direct or inverted repeated sequences leading to extrachromosomal circular or linear amplified DNAs. This ability of *Leishmania* to respond to drug pressure by CNVs has led to the development of genomic screens such as Cos-Seq, which has the potential of expediting the discovery of drug targets for novel promising drug candidates.

Introduction

Leishmania are dimorphic parasites living as extracellular promastigotes in the digestive tract of *Phlebotomus* or *Lutzomyia* sandflies and as intracellular amastigotes within phagocytic cells (mainly macrophages) of the vertebrate hosts. *Leishmania* species cause leishmaniasis, the second largest parasite killer; there are 1.3 million new cases annually, 12 million people are affected worldwide, and 350 million people are currently at risk[1]. The *Leishmania* genus includes several species, among which more than 20 are pathogenic to humans[2]. *Leishmania* can be divided into two subgenera: the *Leishmania Leishmania* subgenus responsible for visceral and cutaneous leishmaniasis and the *Leishmania Viannia* subgenus often associated with either cutaneous or muco-cutaneous forms of the disease[2]. Visceral leishmaniasis is mainly caused by *L. donovani* and *L. infantum* and is characterized by fever, hepatosplenomegaly, and pancytopenia[3], making it the most severe and deadly form of the disease when compared with the self-healing but nonetheless debilitating skin lesions of cutaneous leishmaniasis[4,5].

No effective human vaccine is currently available against *Leishmania* (a canine *Leishmania* vaccine was recently registered in Europe[6]), and control measures mainly involve chemotherapy[7–9]. Pentavalent antimony (Sb) has been the standard drug for 70 years and remains the mainstay in many endemic regions, apart from Northern India, where antimonial formulations have been rendered obsolete because of widespread parasite resistance. Other first-line therapies include the polyene antibiotic amphotericin B (AMB) for which a single dose was shown to be 95% effective against visceral leishmaniasis in India[10]. Liposomal AMB has become a standard treatment in many countries[11] but requires administration by the intravenous route. Geographical differences in the response to liposomal AMB were reported, and visceral leishmaniasis cases in India were more responsive than those from East Africa or South America[12]. Clinical AMB resistance is scarce and parasites remained susceptible even after multiple rounds of treatment in the same patient[13]. The alkyl-lysophospholipid analogue miltefosine (MTF) is the only oral drug against *Leishmania*[14,15]. It has been successfully used for the treatment of visceral leishmaniasis since its registration in 2002 in India[16]. However, relapse rates are on the rise in India[17,18] and Nepal[19,20], making MTF resistance a likely problem. The aminoglycoside paromomycin (PMM) is also approved for the treatment of visceral leishmaniasis in India[21,22]. So far, the scarce use of PMM has limited the emergence of resistance, but geographical variations in PMM efficacy against visceral leishmaniasis were noted between East Africa (especially Sudan) and India[23,24]. Lastly, pentamidine (PTD) has been abandoned for the treatment of visceral leishmaniasis because of serious toxicities and is mainly restricted to patients with cutaneous leishmaniasis in South America[25–27].

Despite six decades of use, the mode of action (MOA) of antimonials is not known. It has been shown to lead to the production of reactive oxygen species[28–31], the depletion of trypanothione[32], and apoptosis-like death[33–36], but an exact MOA is still awaited. The same applies for MTF, AMB, PTD, and PMM, with the possible exception of AMB, which kills *Leishmania* by forming pores in ergosterol-containing membranes. New molecules with well-defined drug targets are clearly needed.

Leishmania and its genome

The *Leishmania* genome is around 32 Mb and displays over 8,300 coding genes[37,38]. Within the *Leishmania* genus, gene synteny is conserved for more than 99% of genes between *L. major*, *L. infantum*, and *L. braziliensis*, and only few species-specific genes were found[38]. *Leishmania* species have between 34 and 36 chromosomes ranging in size from 0.3 to 2.8 Mb[37–41]. One unique feature characterizing trypanosomatid parasites lies in their genome architecture, their protein-coding genes being organized as large polycistronic units[42,43]. In the absence of defined RNA polymerase II promoters, transcription of the long polycistronic units occurs in a bidirectional fashion from transcriptional start sites located at strand switch regions[43,44]. Processing into individual messenger RNAs (mRNAs) occurs by the addition through *trans*-splicing of a spliced leader RNA (39 nt) to the 5′ ends of each mRNA, coupled to 3′ end polyadenylation[45,46]. Because of its lack of transcriptional control, *Leishmania* uses several adaptive mechanisms to regulate gene expression when facing changing environmental conditions during its development. 3′ untranslated regions (3′ UTRs) were shown to be major players in monitoring mRNA stability and translation rates in this parasite[47–53]. To overcome stressful conditions like drug pressure, *Leishmania* also often relies on DNA copy number variations (CNVs) (aneuploidy, gene amplification, or gene deletion) for regulating the expression of drug targets, drug transporters, or other determinants of resistance. This is not restricted to *Leishmania*, however, and variations in gene dosage or chromosome copy numbers also influence drug susceptibility, adaptability, and proliferation in fungi and cancer cells[54–57]. In addition to CNVs, single-nucleotide polymorphisms (SNPs) in drug targets or in transporters can lead to drug resistance without the need for altering gene expression.

Copy number variations

During the last few decades, *Leishmania* parasites were considered to be essentially diploid but recent data have shown that aneuploidy seems to be the norm[58–64]. Within populations of *Leishmania* parasites, distinct aneuploidy patterns were shown to occur at the level of individual cells. This phenomenon was called mosaic aneuploidy and can translate into a seemingly average diploid population when the cumulative ploidy is derived from next-generation DNA sequencing data but in which few parasites actually share the same ploidy for individual chromosomes[62,63,65]. Interestingly, variations in the size and content of chromosomes have also been observed between different strains of the related trypanosomatid parasite *Trypanosoma cruzi*[66,67]. In the case of *Leishmania*, circumstantial links between the presence of supernumerary chromosomes or chromosomal losses and drug resistance have been observed[58–60,64,68–71], suggesting that a particular group of genes on the variant chromosomes may possibly act together in establishing resistance, but this has yet to be demonstrated.

Aneuploidy is generally linked to developmental abnormalities as best exemplified by the trisomy 21 syndrome in humans. However, *Leishmania* uses aneuploidy as a lifestyle. This is raising a number of questions about aneuploidy generation, stability, transmission, and biological significance (reviewed elsewhere[60,62,72]). In the absence of transcription initiation control, increases (or decreases) in chromosome copy number may serve as a strategy for regulating expression under environmental cues. This can happen at the level of whole chromosomes, and indeed there was a good correlation between chromosome ploidy and the level of DNA and RNA expression[59]. Increasing the copy numbers of entire chromosomes may lead to the overexpression of toxic genes, but the *Leishmania* genome (32 Mb) is spread in 34 to 36 chromosomes, thus reducing the co-expression of many genes. However, as explained in detail below, *Leishmania* also has the ability to amplify (or delete) specific smaller regions of DNA as part of extrachromosomal elements by recombination/rearrangements at the level of homologous repeated sequences (RSs). RNA levels derived from these amplifications are correlated to DNA copy number.

The genome of *Leishmania* is populated with repeated DNA sequences. A recent study highlighted the entire set of RSs in different *Leishmania* species, and it was found that the whole *Leishmania* genome has the potential to be rearranged at the level of those RSs for generating extrachromosomal elements[73]. Indeed, almost 2,000 RSs are distributed over the genome of *L. infantum* and these potentially support the formation of more than 3,000 extrachromosomal DNA elements[73]. Short interspersed degenerate retroposons (SIDERs) account for up to 65% of all RSs. SIDERs are truncated versions (~0.55 kb) of formerly active retroposons that are predominantly located in 3′ UTRs and have been associated with post-transcriptional regulation at the levels of both mRNA stability and translation[47,48,52,53,74,75]. Because SIDERs are degenerated, they were found in different RS groups. Remarkably, SIDER elements would have dual roles: one functional by regulating gene expression and a second one structural, providing the backbone to facilitate gene rearrangements for changing copy number of chromosomal DNA regions.

Extrachromosomal DNA amplifications are frequently detected in *Leishmania* parasites challenged with drugs or other stressful conditions[58,59,64,76–87]. The episomes are amplified as either circular or linear extrachromosomal DNA and formed through rearrangements at the level of direct or inverted homologous RSs, respectively (Figure 1)[73,80,88]. Interestingly, between 60% and 80% of the predicted amplicons appear to be already present in the population in the absence of selection and these pre-existing stochastic gene amplifications were shown to foster the selection of adaptive traits in response to drug pressure[73]. Beneficial amplicons were shown to increase in abundance upon higher drug pressure and to decrease when the drug is removed, allowing parasites to respond to a changing environment[73].

Since gene rearrangements through RSs are primary responses to drug pressure, a reasonable hypothesis was that identifying recombinase proteins involved in these rearrangements could lead to strategies to prevent the emergence of resistance. A first candidate was the RAD51 DNA repair protein, a key protein involved in homologous recombination (HR), a mechanism evolutionarily conserved in trypanosomatids[89]. Interestingly, the expression of RAD51

Figure 1. Potential mechanisms for gene amplification in *Leishmania*. (**a**) The RAD51 recombinase mediates homologous recombination between direct repeated sequences (DRS) and leads to (i) extrachromosomal circular amplicon or (ii) intrachromosomal tandem duplication by unequal sister chromatid exchange or RAD51-mediated break-induced replication. Black arrows represent DRS. (**b**) The MRE11 nuclease processes DNA ends after single-strand break (SSB), double-strand break (DSB), or hairpin formation during replication and leads to extrachromosomal linear amplification. Black arrows represent inverted repeated sequences (IRS). The green segments represent the amplified DNA regions. dsDNA, double-stranded DNA; ssDNA, single-stranded DNA.

was induced in *Leishmania* by DNA double-strand breaks (DSBs)[90,91]. Inactivating RAD51 led to viable parasites unable to generate circular extrachromosomal elements but still capable of producing linear amplicons upon drug pressure[73]. *Leishmania* has three RAD51 paralogs (RAD51-3, RAD51-4, and RAD51-6) that were shown to work as a complex in promoting HR through their capacity to stimulate RAD51 activity[92]. Inactivation of RAD51-4 was also shown to prevent the formation of circular amplicons in *L. infantum* exposed to drugs, but not of linear amplicons[92].

Linear amplicons are formed by the annealing of RSs found in an inverted orientation[64,73,93]. MRE11 is a DNA repair nuclease that interacts with RAD50 and NBS1 to form the MRN complex[94,95] and is important for DSB repair by HR[96,97] or for non-homologous end joining[89] (Figure 1b). Inactivation of MRE11 impaired the ability of *L. infantum* to form linear amplicons upon drug selection at the level of inverted RSs, although the capacity to generate circular amplicons was similar to that of wild-type parasites[93]. Moreover, a fully functional MRE11 is important for linear amplification, as parasites expressing DNA-binding-proficient but nuclease-deficient MRE11 exclusively generated circular amplicons during drug selection[93]. Interestingly, inactivation of MRE11 alone or along with its partner RAD50 led to extensive chromosomal translocation in *L. infantum*[98], showing that the MRE11/RAD50 complex is important for the maintenance of genome integrity in addition to its role in gene rearrangements. The number of enzymes involved in the formation of extrachromosomal elements suggests that targeting this pathway may not be a viable strategy for preventing the emergence of resistance, although this remains to be experimentally tested.

Single-nucleotide polymorphisms and small nucleotide insertions or deletions

Although CNVs are important contributors of drug resistance, SNPs and small nucleotide insertions or deletions (indels) can also contribute to resistance. This was proven with experimental drugs[99,100] and was highlighted with MTF where amino acid substitutions or non-sense mutations were observed in the MTF transporter (MT)[101] or in its Ros3 subunit[102]. This was further confirmed in additional mutants using whole genome sequencing[103,104] or by deep sequencing of MT[105]. Mutations detected in the MT gene of *L. infantum* isolates serially collected from an MTF-treated patient who had multiple relapses were shown to correlate with resistance[106], suggesting that MTF resistance could become a clinical reality in the near future.

Genome-wide surveys of genetic variations in *L. donovani* isolates from the Indian subcontinent supported the notion that resistance to antimonials emerged on several distinct occasions[58,107]. Isolates could also be clustered on the basis of their genetic structure and haplotypes, with some groups being enriched for non-responsive strains[58,107,108]. Interestingly, a particular group of highly resistant isolates that clustered together were found to share genomic features associated with resistance[107]. Among these were a higher copy number for the H-locus, coding for the well-characterized ABC transporter MRPA[109], and a homozygous two-base-pair insertion in the aquaglyceroporin 1 (AQP1) gene involved in Sb uptake and whose inactivation or downregulation is strongly correlated with resistance[71,107,110–117]. The potential for these genomic variants in predicting treatment outcome is exciting, given the lack of molecular markers for Sb resistance, but will need to be thoroughly evaluated by using larger and geographically diversified sets of well-defined isolates.

Exploiting copy number variations for understanding drug mode of action and resistance mechanisms

Target-based assays and phenotypic whole-cell-based assays are the cornerstones of drug discovery. The current trend for anti-parasitic agents is for whole cell assays. A drawback of phenotype-based assays is the lack of knowledge about the targets of hit compounds. Although the molecules could be brought to the clinic without further knowledge about their MOA, a clear understanding of the molecular targets will facilitate the improvement of a candidate drug through lead optimization. Characterization of drug-resistant mutants, which often revealed mutations or CNVs in drug targets or in proteins responsible for drug transport, is one strategy to pinpoint drug targets. However, it is salient to point out that this strategy has not yet led to targets against the current anti-leishmanials, although amplification of gene targets was observed in mutants made resistant to experimental drugs[64,99]. Since CNVs are often associated with resistance, forward genetic tools can experimentally mimic this. One such gain-of-function screen was based on functional cloning where *Leishmania* cosmid libraries were electroporated into *Leishmania* and these transfectants were selected for a specific phenotype[118]. Selection is possible because of the high copy number (and gene expression) of the cosmids. This screen was successfully applied while selecting for drug resistance or susceptibility[101,114,119–123]. This technique selects for cosmids conferring dominant phenotypes (leaving out less enriched cosmids) and is not easily amenable to high-throughput screening. The sensitivity of cosmid-based functional screening was enhanced by its recent coupling to next-generation sequencing in an approach termed Cos-Seq[124]. The proportion of parasites with cosmids providing a selective advantage is expected to rise with increasing drug pressure, and these can be tracked and quantified at each drug increment by Illumina sequencing[124,125]. Thus, the dynamics of cosmid enrichment can be followed over the entire course of selection instead of being monitored only at endpoint. Published or ongoing Cos-Seq screens using experimental drugs with known targets (for example, methotrexate, terbinafine, and 5-fluorouracil) confirmed the recovery of the relevant target genes by Cos-Seq[124]. Interestingly, Cos-Seq supported the hypothesis that the current anti-leishmanials (MF, AMB, Sb, PMM, and PTD) may not act via specific major protein targets[124]. Indeed, although an unprecedented number of resistance genes (known and novel) were isolated using Cos-Seq, none emerged as a clear target candidate and it is conceivable that these antiquated drugs are broadly cytotoxic by disrupting multiple minor targets. Whether some of the genes are genuine drug targets remains to be established, and non-protein targets represent another possibility as these would not be detected by Cos-Seq.

The advent of high-content screening for intracellular *L. donovani* amastigotes[126] is also key in the search for novel molecules having favourable anti-leishmanial properties directly on the intracellular stage of the parasite. This allowed the discovery of

192 new leads against visceral leishmaniasis from an initial set of 1.8 million compounds from GlaxoSmithKline[127]. An MOA could be hypothesized for 80 of the lead compounds using prior proprietary knowledge and bioinformatics analyses of TriTryp genomes, which revealed an over-representation of putative kinase inhibitors[127]. Cos-Seq was initially carried out with the insect form of the parasite but this could easily be adapted to intracellular parasites and this technique could be used to find the targets of these promising novel molecules or of other drugs repurposed against *Leishmania*[128].

The Cos-Seq technique does not allow the isolation of loss-of-function mutations such as those found in the aquaglyceroporin AQP1 or in the MT transporter genes (see above). These require high-throughput dominant negative screening approaches, like inducible RNA interference target sequencing (RIT-Seq), which proved instrumental in elucidating mechanisms of drug uptake in trypanosomes[129]. Although RNA interference is absent from the *L. Leishmania* subgenus, it is active in species of the *L. Viannia* subgenus[130]. The lack of inducible expression in *Leishmania* was also a limitation of this technique, but two recent reports have shown the feasibility of inducible expression in *Leishmania*[131,132]. Thus, it is theoretically possible to develop a technology similar to RIT-Seq in *L. Viannia* parasites. An alternative approach to RIT-Seq would be to rely on RNA-guided nuclease systems using clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR-associated (Cas) enzymes, as these have proven very efficient for achieving targeted genomic modifications in a wide range of genomes[133–135]. In trypanosomatid parasites, the CRISPR/Cas9 system derived from *Streptococcus pyogenes* has been used for disrupting genes in *L. major*[136], *L. donovani*[137], and *T. cruzi*[138] and in principle could be used for generating whole-genome Cas9-mediated gene deletion libraries.

Concluding remarks

The toolkit for drug target discovery and resistance mechanism elucidation for *Leishmania* is expanding. With new promising drug candidates in the pipeline and further technological developments, it should now be possible to find new targets which should further help in the control of this important neglected tropical disease.

Editorial Note on the Review Process

F1000 Faculty Reviews are commissioned from members of the prestigious F1000 Faculty and are edited as a service to readers. In order to make these reviews as comprehensive and accessible as possible, the referees provide input before publication and only the final, revised version is published. The referees who approved the final version are listed with their names and affiliations but without their reports on earlier versions (any comments will already have been addressed in the published version).

The referees who approved this article are:

The sight is one of the five senses allowing an autonomous and high-quality life, so that alterations of any ocular component may result in several clinical phenotypes (from conjunctivitis to severe vision loss and irreversible blindness). Most parts of clinical phenotypes have been significantly associated with mutations in genes regulating the normal formation and maturation of the anterior segments of the eye. Among the eye anterior segment disorders, special attention is given to Glaucoma as it represents one of the major causes of bilateral blindness in the world, with an onset due to Mendelian or multifactorial genetic-causative traits. This review will point out the attention on the Primary Congenital Glaucoma (PCG), which is usually transmitted according to an autosomal-recessive inheritance pattern. Taking into consideration the genetic component of the PCG, it is possible to observe a strong heterogeneity concerning the disease-associated loci (*GLC3*), penetrance defects, and expressivity of the disease. Given the strong PGC heterogeneity, pre- and posttest genetic counseling plays an essential role in the achievement of an appropriate management of PCG, in terms of medical, social, and psychological impact of the disease.

1. Introduction

The sight is one of the five senses allowing an autonomous and high-quality life. Hence, sight defects may turn out to be really restricting for the life quality, representing a discriminating or even a life-threatening issue, especially in developing countries. As a matter of fact, about the 75% of information we receive about the world around us relies on the ability of the eyes to receive the light and transform it into a "picture" [1].

Given the critical importance of the sight organ, it is not surprising that alterations or malformations of any ocular component may result in several clinical phenotypes, ranging from conjunctivitis to Cataract until the severe vision loss and the irreversible blindness. Ocular clinical syndromes may develop owing to environmental agents (infections acquired during pregnancy or later in the life, aging processes, and systemic disorders), which can affect the ocular structures at the developmental or mature stages. However, most parts of clinical phenotypes have been significantly associated with mutations in genes regulating the normal formation and maturation of both posterior and anterior segments of the eye [2]. This review will be particularly focused on the genetics and genomics of the anterior segment disorders.

2. Genetic and Phenotypic Overview on the Eye Anterior Segment Mendelian Disorders

The clinical manifestations characterizing the anterior segment disorders reflect both phenotypic and genotypic heterogeneity, with multiple overlapping symptoms and associated genes [3]. Firstly, it is important to distinguish the anterior segment disorders characterized by a Mendelian or simple genetics from the disorders developed in consequence of complex or multifactorial traits. In particular, while the Mendelian diseases are due to causative rare mutations in specific genes (causative gene) and are inherited according to Mendel's laws, multifactorial diseases are caused by an interplay between several genetic and environmental triggering factors [2, 4]. In the large majority of cases, the genetic variants, associated with multifactorial diseases, are not rare mutations but rather polymorphisms, located on susceptibility genes and reported at high frequencies in normal/nonaffected population. These genetic markers are not sufficient to cause the disease but they only represent risk factors, determining a higher susceptibility to a particular disease. As mentioned below, it is interesting to notice that the presence of modifier genes, polymorphisms, or mutations may also be responsible for the variable expressivity occurring in Mendelian and complex diseases [5, 6]. In addition, the recognition of the distinctive features related to each anterior segment disorder can be complicated by different factors [5] such as

(i) the presence of extraocular (systemic) clinical manifestations, as facial dysmorphisms, dental dysplasia, redundant preumbilical skin, and short stature;

(ii) heterogeneous inheritance patterns (mainly autosomal-dominant and/or autosomal-recessive inheritance patterns);

(iii) developmental abnormalities occurring during embryogenesis and maturation of the eye anterior segment tissues (leading to congenital diseases);

(iv) foreign events, such as inflammations, infections, and trauma.

Among the most studied Mendelian diseases, it is important to mention Axenfeld-Rieger syndrome (ARS, #180500, #601499, and #602482), a rare disorder which affects 1 : 200.000 individuals and follows an autosomal-dominant inheritance pattern. The ARS etiopathology is characterized by an abnormal development of the anterior chamber, the cornea, and the iris. Clinical hallmarks of the disease include hypoplasia, corectopia, polycoria, posterior embryotoxon, and peripheral anterior synechiae (iris strands). Facial, dental, umbilical, and skeletal defects are also usually present as extraocular manifestations [5, 7].

Another Mendelian disorder affecting the anterior segment of the eye is referred to as Peters' Anomaly (#604229). It presents a heterogeneous inheritance, mostly autosomal-recessive, although autosomal-dominant and sporadic cases have been reported. The disease is caused by an incomplete separation of the cornea from the iris or the lenses, resulting in a variable central corneal opacity among patients. Systemic abnormalities reported in patients with Peters' Anomaly are short stature, cleft lip palate, growth, and mental delay [5, 8].

The complete or partial absence of the iris results in a pathological phenotype known as Aniridia (#106210). It affects 1 : 50.000–100.000 newborns worldwide and it is inherited in autosomal-dominant pattern. Aniridia is characterized by a reduced visual acuity and photophobia. Suddenly, it is associated with behavioral problems, developmental delay, and difficulties in detecting the odors [5, 9].

Concerning the disease phenotypes associated with malformations of the sclera and the cornea, it is important to mention the Sclerocornea and the Megalocornea. Sclerocornea (#18170) is a congenital disorder characterized by the absence of separation between sclera and cornea, which presents, as a consequence, a flat curvature. The malformation results in a nonprogressive corneal opacification (peripheral, sectoral, or central) [5, 10]. Megalocornea (#309300) instead is generally inherited in an X-linked recessive pattern and it consists of an enlargement of the corneal diameter (>13 mm) at birth, a deep anterior chamber, and normal IOP [5, 11].

Among the anterior segment disorders, particular attention has been paid to Keratoconus and Glaucoma, since both of the diseases are characterized by the presence of both Mendelian and multifactorial traits which give rise to different forms of Keratoconus and Glaucoma.

Keratoconus (#148300) is a noninflammatory degenerative disorder of the cornea affecting 1 in 2.000 individuals. The disease is due to the bulging and distortion of the corneal curvature and surface, which lead to the loss of visual acuity. A number of environmental factors have been associated with the development of Keratoconus, especially long-term contact lens wear, chronic eye rubbing, and atopy of the eye. However, the observation of familiarity transmission and studies on monozygotic and dizygotic twins have demonstrated that Keratoconus is characterized by a significant genetic component. In fact, the disease showed to be mostly transmitted in an autosomal-dominant inheritance pattern, although reduced penetrance and autosomal-recessive transmission have been reported [12].

Concerning Glaucoma several types of diseases can be distinguished, depending on the presence of causative Mendelian or multifactorial characters. In multifactorial Glaucoma, the clinical phenotype originates from the interaction between genetic/molecular (*LOXL1* genetic polymorphisms/retinal ganglionic cell death) and environmental (aging, diet, stress, and life-style) factors [13–15]. Although the hereditary component of the disease remains poorly understood, it is known that it can affect both genders, with higher risk for male subjects, advanced age people, and African descendants [16]. This form of Glaucoma is quite similar to several multifactorial, chronic, and age-related degenerative diseases, such as Osteoporosis, Osteoarthritis, Alzheimer's Disease, Coronary Artery Disease, Cataract [17]. In fact, multifactorial Glaucoma is a chronic neurodegenerative process, with an onset in the middle age and a slow progressive course, without particular signs or symptoms. Subjects affected by Glaucoma show a reduction of the visual field, blurry vision, decreased sensitivity to color, and contrast [16]. Over the multifactorial form, it is important to remark the existence of Glaucomas which are characterized by Mendelian inheritance (mainly autosomal-recessive and autosomal-dominant). Further details about clinical and genetic profile of Mendelian disease will be hereafter given.

Over the phenotypic manifestations of the anterior segment diseases, it is important to take into consideration the genetic background of these disorders. In fact, traditional linkage and positional cloning approaches identified a number of "modifier genes" associated with the development, inheritance pattern, variable expressivity, and phenotype of the anterior segment disorders. Such genetic modifiers consist of mutations or polymorphisms in specific genes, involved in the pathological mechanisms responsible for the disease phenotype [5, 13]. However, the identification of disease-causative genes led to the observation that not only is more than one gene mutation accountable for the same clinical condition, but also variable expressivity and incomplete penetrance can occur in patients carrying the same mutation. In addition, Genome Wide Association Studies (GWAS) allowed the identification of other genetic modifiers, especially common genetic variants associated with the individual susceptibility to eye anterior segment disorders. Each disease-associated individual variant confers a low risk when taken alone, while a set of low-risk variants provide a higher predictive value of the overall susceptibility to the disease [5]. The genes involved in the pathogenesis of these disorders include transcription factors in the majority of cases, although some genes code for transporters and glycosylation proteins. Given their function, mutations in the disease-causative genes will obviously have an impact on the downstream gene regulation, the integrity of the mature protein, and its final interaction with the cellular compartments [18]. The common low-risk variants instead are mostly located in noncoding regions (>80%) near the causative genes and essentially affect the overall gene expression patterns (regulation of RNA splicing and transcription activities) [5]. The variability of the gene expression profile can also be altered by epigenetic events (DNA methylation, histone acetylation/deacetylation, and structural chromatin modification), which act on the DNA transcription rather than on the primary DNA sequence [19]. In particular, DNA methyl transferases (DNMTs) were found to be differentially expressed in tissues and related cells of the eye anterior segment, such as the cornea, conjunctiva, anterior lenses, and trabecular meshwork [19]. Altered methylation profiles have been associated with few anterior segment disorders (such as Pterygium, #17800) [20]. Moreover, experiments on human cells and animal models demonstrated that histone modifications (HDA3) and miRNAs (miR29, miR204, miR146a, and miR24) play a role in the development of anterior segment diseases (as the Primary Open Angle Glaucoma, #137760) [21]. However, further research may help to study and discover epigenetic pathways concerning the etiopathogenesis of the congenital disorders affecting the eye anterior segment.

Independently of the phenotype/genotype features of the disorders, it is important to underline that a pathological phenotype does not result from the disruptive effect of one single gene mutation, but from the alteration of the network of genes to which the mutated gene specifically belongs. As a matter of fact, the high phenotypic and genotypic heterogeneity of the anterior segment disorders of the eye is actually the final outcome of the cross-talking between the disease-causative genes and the individual surrounding environment [5].

2.1. The Genes Causative of the Eye Anterior Segment Disorders. To date, a number of causative genes have been involved in the pathogenesis of the eye anterior segment disorders, some of which will be briefly described in the following paragraphs.

Both genes *PITX2* and *FOXC1*, located at 4q25 and at 6p25, respectively, code for two transcription factors (Pituitary Homeobox 2 and Forkhead Box C1). Linkage analysis has discovered that specific types of mutations in these genes are associated with specific pathological phenotype. In fact, intragenic mutations and/or deletions in *PITX2* and *FOXC1* have been reported in ARS syndrome with or without systemic anomalies. Copy Number Variation (CNV) has been found in ARS and Peters' Anomaly, while missense mutations have been identified in patients affected by Peters' Anomaly [3, 22].

PAX6 was the first gene to be associated with human anterior segment disorder. The gene is mapped on 11p13 and encodes for the transcription factor Paired Box 6. The mutational spectrum of the gene includes nonsense, splicing, insertion, and deletion mutations, resulting in the Aniridia disease. However, some missense mutations in *PAX6* have been reported in Peters' Anomaly and other ocular defects [18, 22].

B3GALTL is located on 13q12.3 and is responsible for the beta-1,3-glucosyltransferase (B3Glc-T) enzyme production, which is involved in the glycosylation process of proteins (posttranslational addition of sugar molecules). Deletion and splicing mutations have been reported in patients with Peter Plus Syndrome (PPS, #261540, Peters' Anomaly with variable systemic anomalies) [5, 22].

SOX2 is mapped on 3q26.3-q27 and codes for the transcription factor SRY-like box 2. It is especially involved in the development of the eyes, so that *SOX2* mutations have been associated with Sclerocornea and other ocular diseases [18].

CHRDL1 is located on Xq23 and encodes for the ventroptin protein, which works as bone morphogenic protein antagonist. Genomic techniques have associated mutation in *CHRDL1* with the X-linked form of Megalocornea [18].

VSX1 is situated on 20p11.21 and produces the transcription factor Visual System Homeobox 1. It is functionally involved in the regulation of the events occurring during craniofacial and ocular development. Missense mutations were found to be involved in the pathogenesis of Keratoconus, particularly concerning the autosomal-dominant form with variable expressivity and incomplete penetrance [12].

Other genes related to the above-mentioned and other eye anterior segment disorders (not described in this review) include *FOXE3*, *BMP4*, *BMP7*, *LAMB2*, *COL4A1*, *FGFR2*, *CYP1B1*, *LTBP2*, and *MYOC* [22].

In particular, this review will be focused on the genetic components underlining the congenital form of Glaucoma, a rare pathological condition affecting the anterior chamber drainage structures of the eye.

3. Focus on a Specific Disorder of the Anterior Segment of the Eye: The Glaucoma

As mentioned above, in the context of the eye anterior segment disorders special attention is given to Glaucoma. It represents one of the major causes of bilateral blindness in the world and several types of diseases have been classified to date, according to presence of Mendelian or multifactorial genetic-causative traits. In particular, Glaucoma consists of a pathological condition characterized by the progressive death of Retinal Ganglion Cells (RGCs), degeneration of the optical nerve, and vision loss as final result. The real explanation for RGCs death is not yet clear, although the level of IOP is known to play a fundamental role [13]. In particular, the IOP depends on the homeostasis between the aqueous humor produced in the ciliary body (and secreted in the posterior chamber) and its drainage through the trabecular meshwork in the anterior chamber angle. The balanced production and outflow of aqueous humor are constant and generate a positive pressure within the eye (~15 mmHg). Malfunctioning and/or malformations of the trabecular meshwork may result in the elevation of IOP over the limit ranges (>21 mmHg) and consequently the development of Glaucoma. Trabecular meshwork disruption can depend on a number of factors, such as mechanical and oxidative stress, aging, and genetic mutations [23]. The improper drainage of aqueous humor determines the increase of IOP, which in turn generates a mechanical stress and strain on the lamina cribrosa (the exit points of the optic nerve fibers in the sclera). The resulting stress blocks the transport of neurotrophic factors to the RGCs that finally die by apoptosis [24].

Glaucoma can be classified into primary, secondary, and primary congenital. The primary form is a nonsyndromic condition and it does not originate from any previous anterior segment abnormality, trauma, or inflammation. According to the compromised regions, two types of primary Glaucoma can be distinguished: Primary Closed-Angle Glaucoma and Primary Open-Angle Glaucoma. In the first condition, the drainage of aqueous humor is clogged by the closure of the angle between the iris and the cornea, while in the second form the fluid meets high resistance because of a malfunctioning of the trabecular meshwork [23].

The secondary Glaucoma instead is linked to the presence of ocular injuries or systemic conditions (for example, diabetes and long-term corticosteroid use) [23]. Even in this case, Closed-Angle and Open-Angle subtypes can be distinguished. On this subject, the Pseudoexfoliation Syndrome (PEXS) represents one of the major causes of secondary Open-Angle Glaucoma (accounting for the 25% of all Open-Angle Glaucomas). PEXS is described as an age-related systemic disease, which leads to the development of the secondary Glaucoma because of the accumulation of exfoliation material in the trabecular meshwork and consequently the increase of IOP [14].

This review will point out the attention on the Primary Congenital Glaucoma (PCG) which is a rare form representing the 1–5% of all cases of Glaucoma [25]. PCG generally presents an autosomal-recessive inheritance pattern, so that it affects only the 25% of newborns from parents carrying PCG-associated mutations. However, the incidence of PCG is highly heterogeneous in relation to the population, the geographic region, and the prevalence of consanguineous relationships. In fact, the incidence rate is estimated to be 1 : 2.500 in Saudi Arabia and Slovakia Gypsy populations (because of highly frequent consanguineous relations), in contrast with the lower incidence rate recorded among Western populations ranging from 1 : 18.500 and 1 : 30.000 [25, 26].

On the basis of the age of onset, it is possible to classify three subtypes of PCG: neonatal or newborn when presented at the birth or within the 1st month of life; infantile, diagnosed from 1st month to 2 years; and late-onset, recognized after 2 years. Usually, in 70–80% of cases, PCG affect both of the eyes (bilateral form) [27].

The clinical hallmarks of PCG diagnosis include IOP > 21 mmHg, optic cupping, epiphora, corneal edema and Haab striae, globe enlargement (buphthalmos), photophobia, blepharospasm, and hyperlacrimation. The PCG phenotype is due to a trabeculodysgenesis phenomenon, that is, an abnormal development of anterior chamber leading to the enlargement of the trabecular meshwork bundles and consequently reduction of the trabecular area available for the aqueous humor outflow [28]. In addition, the humor drainage is reduced because of the interference of immature iris, ciliary body, and anterior chamber angle structure which appear superimposed on the trabecular meshwork and compromise the aqueous humor outflow. The final result of these anterior segment structural defects and the altered aqueous humor drainage is the elevation of IOP and the enlargement of the entire ocular globe [25].

4. Genetics of PCG

Taking into consideration the genetic component of the PCG, it is possible to observe a strong heterogeneity in terms of disease-associated loci, penetrance defects, and expressivity of the disease among the different populations. Concerning the disease-associated loci, the Human Genome Organization established a specific nomenclature for Glaucoma-associated genetic loci. In fact, "GLC" stands for the general name of genes involved in Glaucoma; "1, 2, and 3" indicate the type of primary Glaucoma (Open-Angle, Closed-Angle, and congenital/infantile Glaucoma, resp.); "A, B, C, and D" refer to the progressive genes mapped for each Glaucoma type [26]. This review will focus particularly on *GLC3* loci, since these refer to the primary congenital Glaucoma.

4.1. GLC3 Loci. To date four PCG loci have been classified under *GLC3* subgroup, namely, *GLC3A*, *GLC3B*, *GLC3C*, and *GLC3D*.

The first locus to be associated with PCG was *GLC3A*, mapped on 2p21 chromosomal region. At this locus, about 147 mutations have been found in the gene *CYP1B1*, coding for the homonymous protein (cytochrome P450, family 1, subfamily B, and polypeptide 1) [29, 30]. *CYP1B1* consists of 3 exons and 2 introns, of which the first exon is a noncoding region, while the second and third exons are responsible for the production of CYP1B1 protein [25]. The *CYP1B1* mutations can be missense, nonsense, insertions, and deletions and result in the disruption of enzymatic activity and functionality of CYP1B1 protein [25, 31].

The mutations showed an autosomal-recessive inheritance pattern and are the most common variations identified among PCG patients, especially in consanguineous cohorts. However, a high variable distribution of *CYP1B1* mutations has been reported among the different worldwide populations, with 90–100% found in Saudi Arabia and Slovakia Gypsy populations, 14–30% among USA and European populations, and 15–20% reported in Japanese and Chinese populations [31–33]. Interestingly, in families carrying *CYP1B1* mutations cases of incomplete penetrance and variable expressivity have been observed. In fact, patients harboring the same mutations showed a different degree of disease severity, age of onset, or even lack of the disease phenotype [25, 26].

The pathogenetic role of the CYP1B1 protein in PCG has to be yet clarified, although a possible involvement in the metabolic pathways required for eye anterior chamber development is suggested, particularly for the trabecular meshwork formation [26]. On this subject, a recent study conducted on *Cyp1b1*$^{-/-}$ mice demonstrated that *Cyp1b1* deficiency was responsible for the increased oxidative stress and ultrastructural defects in the TM tissue of early-life animals. In particular, the absence of CYP1B1 protein (due to *Cyp1b1* silencing) hampers the proper removal of Reactive Oxygen Species (ROS) and, consequently, compromises the development and differentiation of TM tissue. In addition, the increased oxidative stress in *Cyp1b1*$^{-/-}$ mice caused the decrease of the Periostin (Postn) production, which results in the loss of the mechanical strength and structural integrity of the TM tissue [34].

GLC3B and *GLC3C* loci have been associated with the PCG, although no gene has been identified in both regions to date. In particular, *GLC3B* is located at 1p36.2–1p36.1 while *GLC3C* maps on 14q24.3–14q31.1 [25, 26].

Concerning the *GLC3D* locus (14q24), autosomal-recessive null mutations have been reported at this position and located in the *LTBP2* gene. *LTBP2* codes for the Latent Transforming beta Binding Protein 2, a matrix protein playing a role in tissue repair processes and cell adhesion. The role of the PCG still remains to be explained. However, it has been demonstrated that *LTBP2* is expressed in the trabecular meshwork and ciliary body and PCG-causative null mutations have been found in consanguineous Pakistani, European Gypsy, and Iranian families [26, 35].

4.2. Other PCG-Associated Genes. Families affected by PCG carried mutations in *MYOC* gene, independently of the presence or absence of *CYP1B1* mutations. *MYOC* is a 3-exon gene, located at 1q24.3–1q25.2 chromosomic region, and codes for the glycoprotein myocilin. The function of the protein is unknown, while its expression has been reported at high level in the trabecular meshwork and the ciliary body. Mutations in *MYOC* have been found to be a leading cause of aqueous outflow obstruction through the trabecular meshwork and of the consequent IOP elevation. A number of *MYOC* mutations have been associated with the juvenile- and adult-onset primary Glaucoma, characterized by an autosomal-dominant/autosomal-recessive inheritance pattern with high penetrance.

Concerning the role of *MYOC* in PGC, possible interactions with *CYP1B1* and/or other unknown loci have been hypothesized to work as genetic modifiers to determine an earlier onset of the disease in patients harboring mutations in *MYOC* and *CYP1B1*, with respect to the patients negative for *MYOC* or *CYP1B1* mutations [25, 26, 36].

Another putative PCG-associated gene is *FOXC1*, a protein expressed in periocular mesenchyme cells, producing ocular drainage structures as iris, cornea, and trabecular meshwork. Interestingly, a deletion in *FOXC1* has been detected in PCG and other ocular and nonocular defects, highlighting a possible involvement of *FOXC1* in the pathogenetic pathway of the disease [25, 26].

Mutations in *BMP4* gene (14q22-q23) have been identified in patients affected by PCG and other disease phenotypes. *BMP4* codes for the bone morphogenetic protein 4 and it is expressed in different tissues, among which is the ocular vesicle, and in the optic cup. However, further research is needed to clarify the role of *BMP4* in PCG pathogenesis [26].

5. The Genetic Counseling in the Management of PCG

As PCG is a severe disease characterized by a particular genetic base and familiarity, genetic counseling represents a useful tool for the disease management (clinical features of the disease, prevision of the disease progression, and medical complications) [37]. Genetic counseling is a communication activity oriented to help the patient and/or their family in receiving medical information concerning the genetic features associated with PCG. In particular, the genetic specialist has to explain the recurrence risk of PCG in relation to the presence of positive/negative familiarity and to the frequency of PCG in the general population. The construction of familiar pedigree may be of help for clarification of the genetic model of inheritance of the disease. In fact, although the majority of cases of PCG appear to be sporadic cases or to follow an autosomal-recessive inheritance pattern, in rare cases some families reported an autosomal-dominant inheritance model. After the clarification of the genetic base of the disease, the recurrence risk and familiarity for PCG have been assessed, and the specialist should suggest and give details about the possibility of performing a genetic test for the detection of PCG-causative mutations. In particular, as illustrated before, mutations in *CYP1B1*, *LTBP2*, and *MYOC* have been found to be causative of PCG among different worldwide populations [25]. However, the specialist has to put in evidence the variable expressivity and penetrance defects occurring in presence of causative mutations. In fact, it is important to clarify to the patient that the positivity for PCG-associated mutations does not always correspond to the development of the effective pathological phenotype and the disease may manifest at later age. In case of presence of PCG-associated mutations, the genetic specialist should suggest to the patient a constant follow-up of his own clinical conditions. This aspect is strongly important in case of siblings of children positive to *CYP1B1* mutations, where there is a 25% higher risk of PCG development because of the variable expressivity of the disease phenotype [25, 38].

To help understand the pros and cons of genetic tests, it is very important to perform the informative counseling prior and after the test (pre- and a posttest). In this context the explanation of biological aspects and technical approaches related to the genetic test may help in understanding limits of negative results, false-negatives, and the need of further investigations.

Unfortunately, some cases may result negative to the analysis of PCG-causative known mutations, so that undiscovered mutations in other unidentified genes may be possible (e.g., unknown genes mapped on *GLC3B* and *GLC3C* loci). Social and psychological implications of the lack of a responsible gene involve the impossibility to perform genetic tests for the prediction of the disease risk in families with a positive-PCG history. This aspect may appear as a "sword of Damocles" and may affect deeply the couple perspective in matter of family construction.

6. Conclusion

The visual loss is due to interruption/aberration/malformation of the normal functioning of the ocular structures. Early-onset ocular diseases usually have Mendelian inheritance, while common adult-onset disorders are inherited as complex traits. To date, several genetic and molecular studies have provided insights into the biological processes underlying many ophthalmic disorders. In this context, GWAS identified different genetic variants contributing to a number of common ocular complex disorders.

Glaucoma is a heterogeneous group of disorders causing irreversible blindness worldwide. As previously described, most forms of Glaucoma present a significant genetic component, characterized by the different causative or susceptibility genes identified through traditional (genetic linkage) or novel (GWAS) approaches. Among the different forms of Glaucoma, we focused our attention on the PCG, that is, the single most common childhood Glaucoma.

PCG is a rare disease affecting the structures of the anterior chamber of the eye anterior segment. Although rare, it is still the most common Glaucoma in infancy and causes a disproportionately high percentage of childhood blindness worldwide. It displays a strong heterogeneity in terms of disease phenotype and genotype. Genetically speaking, PCG presents a familiarity trend, with higher frequency in populations where consanguineous relationships are common (Saudi Arabia and Slovakia Gypsy populations). To date, several mutations in *CYP1B1*, *LTBP2*, and *MYOC* have been associated with the development of the disease, although the expressivity phenotype and the penetrance are variable. Given these data, pre- and posttest genetic counseling has an essential role for an adequate management of PCG, in terms of medical, social, and psychological impact of the disease.

It is important to remark that the eye has been at the forefront of translational gene therapy largely because of the availability of appropriate disease targets and its suitable anatomic features. These advantages have further fostered the research that culminated in the establishment of various clinical trials for the gene therapy of ocular diseases. In this perspective the identification of modifier genes should be encouraged as well as the analysis of the interaction between genes and environmental factors. The challenge for the future is to classify patients in relation to their genetic background, in order to provide personal treatment and management.

Conflict of Interests

Based on artificial intelligence (AI), computer-assisted medical diagnosis can scientifically and efficiently deal with a large quantity of medical imaging data. AI technologies including deep learning have shown remarkable progress across medical image recognition and genome analysis. Imaging-genomics attempts to explore the associations between potential gene expression patterns and specific imaging phenotypes. These associations provide potential cellular pathophysiology information, allowing sampling of the lesion habitat with high spatial resolution. Glioblastoma (GB) poses spatial and temporal heterogeneous characteristics, challenging to current precise diagnosis and treatments for the disease. Imaging-genomics provides a powerful tool for non-invasive global assessment of GB and its response to treatment. Imaging-genomics also has the potential to advance our understanding of underlying cancer biology, gene alterations, and corresponding biological processes. This article reviews the recent progress in the utilization of the imaging-genomics analysis in GB patients, focusing on its implications and prospects in individualized diagnosis and management.

INTRODUCTION

Glioblastoma (GB) is the most common malignant primary brain tumor in adults, accounts for 48.3% of malignant brain tumors (1). Much work has focused on GB, given that it has the characteristics of infiltrating the surrounding brain tissue (2), and has an aggressive course and extremely grim prognosis (3). Gene expression profiling has provided new perspectives for the identification of tumor-associated genetic mutation, biomarkers, and therapeutic targets of glioblastoma (4, 5). The 2016 central nervous system (CNS) tumor classification of the World Health Organization (WHO) incorporated molecular markers into traditionally histopathological classification, providing an integrated phenotypic and genetic classification (6). Recently, based on transcriptomic profiling, GBs have been divided into proneural, classical, and mesenchymal subtypes (7).

The characteristic neuroradiological findings raise the initial suspicion for GB and determine the initial surgical approach and plan. Diagnosis is confirmed through histo-molecular evaluation of the tissue post-biopsy/resection. Traditional magnetic resonance imaging (MRI) has greatly improved the diagnostic efficiency of intracranial lesions, but there are still limitations in the definitive diagnosis of brain tumors. Over the past few decades, there has been a rapid development towards the application of quantitative parametric MRI techniques for GB evaluation (8). More recently, advanced computer technology has permeated the field of modern medicine, making precision medicine an inevitable trend in the development of clinical medicine. Artificial intelligence (AI) is a broad term that covers a wide range of disciplines including computer vision, machine learning, and more. Deep learning is a branch of machine learning that uses artificial neural networks as a framework to learn and characterize databases. There has been growing interest in the application of AI techniques to neuroimaging research, making machine learning and deep learning algorithms critical to the radiomics procedures.

Radiomics utilizes high-throughput radiomics features and mathematical models to quantify tumor characteristics, allowing the non-invasive capture of microscale information hidden within medical imaging (9, 10). As an important branch of radiomics, imaging-genomics (also known as radiogenomics) further links imaging characteristics (phenotypes) with genetic, mutational, and expression patterns (11, 12). The basic hypothesis of imaging-genomics is that the expression of a specific set of genes or molecular alterations affects the extractable imaging phenotypes (13). A particular focus of imaging-genomics analysis has been on the association between imaging characteristics and gene expression patterns, including the expression of individual genes and the expression of specific gene subgroups (14). Just like the resolution and complexity that genomics has brought to tumor biology, imaging-genomics also brings similar effects to traditional medical images. The ultimate goal of radiomics is to maximize the utilization of medical imaging information to help clinicians make clinical decisions, so as to minimize the possibility of potential invasive maneuvers. The increasing importance of genetic markers has also led to the rapid growth of GB imaging-genomics research, with progressively greater complexity, including the combination of artificial intelligence (AI) technology. More recently, deep learning using convolutional neural networks has further improved radiogenomics prediction (15, 16), providing unique opportunities and challenges for the diagnosis and treatment evaluation of GB.

Herein, we will review the latest researches on radiomics and imaging-genomics of GB. First, we briefly introduced the genomic characteristics of GB and the principle of imaging-genomics, and then summarized the findings of the latest research. Finally, we will present our opinions on its current challenges, and potential future directions.

GENOMICS IN GLIOBLASTOMA

Traditionally, GBs can be divided into "primary" and "secondary" GBs. The vast majority of GB (about 90%) develop rapidly *de novo* in elderly patients and are mostly isocitrate dehydrogenase (IDH) wild-type. While secondary GBs develops from a preexisting lower-grade glioma in younger patients and usually carry mutations in IDH (17). Radiologically, primary GBs are widely distributed in the brain, while secondary GBs are preferentially located in the area of the frontal lobe surrounding the rostral extension of the lateral ventricle in younger patients (17, 18). Primary and secondary GBs are largely histologically indistinguishable, but they are different in genetic and epigenetic profiles (17). The genomic and transcriptome characteristics of these tumors have revealed the key alterations that may contribute to the classification and evaluation of the disease (4, 19, 20) (17) (21).Different bioinformatics algorithms have identified several genes as significantly mutated in GB, including but not limited to epidermal growth factor receptor (EGFR), TP53, PTEN, Neurofibromatosis 1 (NF1), and RB1 (20, 21). Additionally, genomic analysis based on multiple sampling from the same neoplasm suggests that transcriptome subtypes are heterogeneous in GB (22) (23). Patient-specific intratumor heterogeneity of GB underlies variation in response to treatment, which contributes to the eventual failure of treatment (22, 24, 25), including drug resistance, radiotherapy resistance, and fast and incurable tumor recurrence. Thus, relying only on single tissue samples from individual patients to understand the cancer dynamics of GB is challenging.

The whole-genome sequence analysis has revealed the genetic and epigenetic landscapes of human brain GB (4, 20). Complex gene interaction events and molecular modulation networks are involved in the occurrence and development of GBs (4, 5, 26). It is expected that one or several biomarkers will provide information to help clinicians make the diagnosis, and enable clinical experts to make the best choice among various treatment options, such as surgery and/or chemotherapy, and/or radiotherapy, and/or targeted therapy. Numerous studies have identified alterations of several core signaling pathways in GB, including the RB1 pathway, the TP53 pathway, and the PI3K/PTEN pathway (4, 21). The heterogeneity of GB cells (26) suggests that targeting strategies based on multiple elements of different signaling pathways might constitute a more efficient therapy for GB (5).

Given its invasive and infiltrating nature, GB is essentially considered to be a disease of the entire brain (27). Surgical biopsy is currently the standard procedure for providing the genomics information of GB. However, a biopsy is not only highly invasive, but its accuracy is also limited by the biopsy site, resection type, and disease variability. Compared with traditional genomic analysis, imaging-genomics has the advantage of assessing the entire tumor volume, and non-invasively provides a "virtual biopsy" by predicting specific gene status, biological processes, and even core signaling pathways of GB (28–30) (28, 29, 31). High-resolution imaging technologies can present the tumor completely and three-dimensionally. Based on this property, imaging-genomics can associate the radiological phenotypes (such as shape or texture) of a specific spatial location (such as necrosis, high perfusion, or even more subtle subregions) with the tumoral molecular characteristics of the same location. Also, by associating the genetic status of the biopsy location with the quantitative imaging features, imaging-genomics has the potential to help characterize tumoral genetic heterogeneity (30), which shows diagnostic value under the context of individualized oncology.

RADIOMICS AND IMAGING-GENOMICS OF GLIOBLASTOMA

Traditional pathology and radiology have been primarily focused on the associations between histopathologic and visual imaging findings, while radiomics and imaging-genomics focus on exploring the relationships between imaging phenotypes and biological characteristics (11, 12). Generally, radiomics is dedicated to discovering the biological significance (such as predicting survival and treatment prognosis) of specific imaging phenotype, which when correlated with genomics is termed imaging-genomics. Imaging-genomics analysis helps to understand the biological associations behind image phenotypes, explain how biological processes are reflected in imaging, and define imaging markers associated with molecular biological characteristics. When constructing an imaging genomic map of GB, several dimensions need to be considered, including the disease course, imaging category, lesion delineation, features extraction and selection, and biological data type, as well as model building or integration (11). Typically, the imaging features used in a radiomics or imaging-genomics study are mainly divided into two categories, namely manually defined features and deep learning features.

Feature Extraction, Selection, and Corresponding Modeling

Manually Defined Features

Manually defined feature-based imaging-genomics utilizes specific mathematical algorithms to extract features from pre-depicted regions of interest (ROI) (**Figure 1**). After feature extraction and feature selection, machine learning models are used to solve classification and/or regression problems. Usually, the steps of the process mentioned above includes a few phases as following: 1) Data acquisition; 2) Image pre-processing, including multiparametric imaging registration, noise reduction, intensity and/or orientation normalization, spatial resampling, and corrections of MRI field inhomogeneities; 3) Segmentation of ROI, segment the tumors into necrosis, enhancement, edema, and peritumoral parts, etc. by manual

delineation or (semi-) automated algorithms; 4) Feature extraction, extract different kinds of quantitative features that reflect the heterogeneity of tumors, including shape features, histogram-based features, textural features, and higher-order statistics features; 5) Feature selection, including supervised and unsupervised methods to overcome the issue of redundancy and overfitting that may be seen with multitudinous features; 6) Model building and evaluation, build a mathematical model (such as regression models, random forest (RF), and/or support vector machines (SVM) based on the selected features to predict a known, underlying ground truth, including specific genetic mutation or pathway alterations. In general, training set data is used for learning to fit the parameters of a classifier, while the validation set is used to tune the parameters of the model. Ideally, after model training and validation, the final models should be applied to the test set (unexposed independent data) to evaluate the performance of the final model. A robust radiomic model must be validated by independent, external data to show its value for clinical promotion and application.

Deep Learning-Based Features

Deep learning, a subcategory of machine learning based on neural networks (32), represents a class of algorithms that use stacked neural network structures (33). In deep learning-based imaging-genomics, different network structures such as auto-encoders or convolutional neural networks (CNNs) are utilized to mine the hidden features from the initial data (15, 34). The typical way to extract deep learning features is to train a deep learning model using observed indicators, and then extract the outputs of specific layers as deep learning features (35). For example, the results of the final fully connected layer of CNNs or the final convolutional layer of auto-encoder can be extracted as deep learning features (36). The extracted deep features can either be trained by an artificial neural network for classification and prediction (15) or leave the network and fit into different classifiers (35) (such as SVM, RF) to generate a model (**Figure 1**), the latter process is similar to the approach of manually defined feature-based imaging-genomics. Recently, deep learning has been successfully applied in digital pathology to segment nuclei and for the classification of molecular markers (37, 38). Deep learning-based imaging-genomics usually requires relatively large datasets. Auto-encoders provide an alternative method to extract deep features when there is not enough data to train a deep learning model (34, 36). Another technique to overcome this limitation is transfer learning (39, 40), which essentially uses a pre-trained network (usually on natural images) to solve the data set needs of deep network training (34). **Figure 1** describes the main workflow of the above two methods, and **Table 1** summarizes several radiomics studies designed according to this workflow.

Imaging-Genomics of Glioblastoma

As a subclass of radiomics, imaging-genomics focuses more on the relationships between imaging characteristics of a disease, and its gene expression patterns, gene mutations, and other genomic-related characteristics (11). The gene expression patterns for constructing these relationships include not only the expression of a single gene (45, 50), but also the measures that summarize expressions of specific gene subsets (14, 29, 51, 52), the corresponding signal pathways (29, 53), and consequent biological effects (28, 54). 'Imaging-genomics' research also refers to a study aimed at discovering those relationships.

In addition to predicting the expression status of specific molecular markers, the current imaging genomics researches can

be divided into several directions. On the one hand, researchers can first identify the prognostic imaging features (like OS or progression-free survival, PFS) to calculate individualized indicators (such as radiomic risk score, RRS), based on which patients will be further classified into different subgroups (low- or high-risk groups). Some bioinformatics analysis methods such as Gene Ontology (GO), Gene Set Enrichment Analysis (GSEA) analysis can be further used to detect differences in molecular biology of different subgroups, corresponding signal pathways, and downstream biological processes (28, 54, 55). Another research paradigm is the reverse process of the above method (13, 56). Bioinformatics analysis can reveal the pathways, biological processes, and expression of protein corresponding to specific molecular markers detected by sequencing technique. These biological processes can finally be mapped in the form of different imaging phenotypes (like necrosis or edema) on multi-modal images, and then captured by the quantitative radiomic features (such as shape, texture, or wavelet). A pioneering radiogenomics study by Zinn et al. (13) showed that radiomic-features could significantly predict periostin expression status in GB patients (Area under the receiver operating characteristic curve, AUC=76.56%) and orthotopic xenografts (AUC=92.26%). The authors tried to establish causality between radiomic texture features and expression levels in a pre-clinical model. This was one of the first radiogenomics studies highlighting a causal linkage between specific gene expression status and radiomic-features of GB. This kind of research paradigm is more suitable for the verification of the radiogenomics model and its corresponding conclusions. However, to date, it has not been elucidated how specific biological processes reflect phenotypes through imaging. Additional multidisciplinary studies in the future are needed to shed more light on this subject. **Figure 2** describes the common steps of an imaging-genomic study and **Table 2** summarizes several imaging-genomic studies in patients with GB.

Although imaging-genomics has broad application prospects, current researches mainly focus on one or several aspects of the procedures and purpose discussed above. Here, we will review the recent progress in the utilization of the imaging-genomics analysis in GB patients.

PROGRESS OF IMAGING-GENOMICS IN GB

Candidate Molecular Alterations

Isocitrate Dehydrogenase 1 and 1p/19q Codeletion

Genetic analysis revealed that the IDH1 gene mutations exist in approximately 12% of GB (21). Tumor-related IDH1 mutations result in the enhancement of enzyme function, which causes the accumulation of R(-)-2-hydroxyglutarate (2HG), and the accumulation of 2HG might drive oncogenesis (60). IDH1 mutation is also an independent factor for predicting the prognosis of patients with glioma (61), and the IDH and 1p/19q codeletion status has been introduced into the revised WHO classification of CNS tumors (6).

There have been numerous studies attempted to reveal the links between the IDH1 and 1p/19q codeletion status with the imaging-phenotypic appearance of GB (15, 38, 41–43). A model for predicting the state of molecular markers (such as IDH1) needs to take into account the distribution of data, considering that the vast majority of GB are IDH1 wild types (17). In this context, some techniques (like the synthetic minority oversampling technique (SMOTE) and adaptive synthetic) have been proven to have better performance in some cases (62). In a study of 225 GB patients by Li et al. (41), after balancing the data with the SMOTE algorithm, the model combining all-region (necrosis, enhancement, non-enhancement, and edema areas) radiomics features with clinical information achieved the best performance of a 97% accuracy. The radiomics model with multi-regional features has the potential to predict the IDH1 mutation status of GB patients, and the data balance is beneficial to improve the classification performance. Li and colleagues (44) used 18F-fluorodeoxyglucos PET scans from 127 patients, after feature selection through least absolute shrinkage and selection operator (LASSO), the final SVM model used 11 features and yielded an area under curve (AUC) of 90% in the validation set. In general, radiomics utilizing multimodal images seems to achieve better performance than a single modality. Nevertheless, there are also exceptions. Using a 3D-Dense-UNets approach, Yogananda et al. (63) reported a mean accuracy of 97.14% in predicting IDH status. Interestingly, the authors demonstrated similar performance when comparing the T2-based network with the multi-contrast network. One possible reason is that the deep-learning networks using conventional single-modality MR images avoid the effect of head motion due to long scan times, which helps promote clinical translation.

Choi et al. combined perfusion and conventional MRI for the prediction of IDH genotype in a group of 463 patients. The authors reported that the long short-term memory model, a type of recurrent neural network (RNN), showed performance with an accuracy of 92.8% in the validation set and 91.7% in the test set (50). Also, the RNN model can provide certain interpretability by demonstrating which temporal features are crucial for the prediction of IDH genotypes. By performing principal component analysis on their final CNN layer, Chang and co-workers (42) selected the imaging features and obtained a prediction accuracy of 94% for IDH status and 92% for 1p19q codeletion. Recently, Choi and colleagues (15) used MRI data from multiple centers to predict IDH genotypes in a cohort of 1,166 patients with glioma (WHO grade II-IV). Researchers developed an automated approach containing two CNN models, one for tumor segmentation and the other for IDH status prediction. Finally, the automated model achieved the highest diagnostic accuracy of 93.8% and 87.9% in the internal and external test set, respectively. A fully automated process is conducive to the repeatability and generalization of results, which reduces the interference of human factors and is beneficial to future application and promotion of the models.

O (6)-Methylguanine-DNA Methyltransferase

The MGMT gene encodes a DNA repair enzyme named O6-alkylguanine DNA alkyltransferase (64). In this process, the methylmoiety is transferred onto the MGMT protein and thus

FIGURE 2 | General workflow of imaging-genomics studies. A imaging-genomics research can generally build the relationship between imaging phenotypes and genetic characteristics from two perspectives. **(A)**, Left semicircle, from imaging phenotypes to genomic characteristics: using features extracted from the sub-areas of tumors in multi-modal images to construct individualized RRS or divide patients into different subgroups, and utilize the corresponding sequencing data for further bioinformatics analysis (such as GO or GSEA). **(B)**, Right semicircle, from genomic characteristics to imaging phenotypes: bioinformatics analysis can reveal the pathways, biological processes, and expression of protein corresponding to specific molecular markers detected by sequencing technique. These biological processes can finally be mapped in the form of different imaging phenotypes (like necrosis or edema) on multi-modal images, and then captured by the quantitative radiomic features (such as shape, texture, or wavelet features). is consumed (64, 65). The epigenetic modification of the cytosine-phosphate-guanine (CpG) island at specific CpG sites of the MGMT promoter silences the gene, resulting in low DNA alkylation repair efficiency and enhanced response to temozolomide (TMZ) (66, 67).

The methylation status of the MGMT gene promoter has been considered as a crucial biomarker of tumor response to TMZ chemotherapy. Consequently, it has become an important molecular marker in imaging-genomics research (68–71). Sasaki and colleagues (72) extracted features from MRI data of 201 newly diagnosed GB patients. The diagnostic model of MGMT promoter using two significant Gray-level Co-occurrence Matrix texture features selected by LASSO only yielded a low accuracy of 67%, which remains insufficient for practical use. Wei and colleagues (45) found that the fusion radiomics signature (clinical factors and texture features) showed great performance for predicting MGMT promoter status of glioma, with an AUC value of 0.902 in the validation cohort. Moreover, the model could classify patients into low-risk and high-risk groups for overall survival (OS) after TMZ chemotherapy, which may serve as a basis for individualized treatment recommendations. Li et al. (46) predicted the MGMT promoter methylation used 1,705 radiomics features from multiregional and multiparametric MRI in multicenter cohorts. The final model achieved an accuracy of 80% in the test dataset. Distinguished from the studies in the past (43), however, this study suggested that combing clinical factors with radiomics features did not improve the prediction performance.

PET-based radiomics is also a promising method to noninvasively evaluate the MGMT status of gliomas. Qian et al. (47) extracted features from PET images of 86 patients with GB. Features were selected by comparing the weighted feature coefficient and filtering with bivariate analysis. The Random Forest model using the appropriate parameters from

the grid search achieved 80% ± 10% accuracy for the prediction of MGMT promoter status. Kong et al. (73) used PET images from 107 patients with WHO grade II-IV primary diffuse gliomas for prediction. Using Wilcoxon ranksum test for features selection, a radiomics signature comprising five final features for the prediction of MGMT promoter status could be identified, yielding an AUC of 0.86 in the validation sets. However, this model lacks further validation on an external dataset.

The CNN-based classifiers achieved the accuracy from 82.7% to 94.9% in predicting the methylation status of MGMT promoter in GB (74, 75). Chen et al. (74) utilized a deep learning pipeline for automatic tumor segmentation and MGMT promoter status prediction in an end-to-end manner for GB patients. The better tumor segmentation and MGMT prediction performance both came from Fluid-attenuated inversion recovery (FLAIR) images. The CNN-based prediction model in this study had only 4 layers and achieved an accuracy of 82.7%, which might be further improved by a deeper network architecture with multi-layers. Korfiatis et al. (75) compared three different residual deep neural network (ResNet) architectures to evaluate their performance in predicting MGMT promoter status in patients with GB. The researchers found that the ResNet50 architecture (the deepest model with 50 layers) outperformed the two shallower architectures (ResNet18 with 18 layers, ResNet34 with 34 layers), and achieved an accuracy of 94.9% in the test set. Networks with deeper architectures could potentially improve the performance of the model, which also increases the risk of overfitting. Transfer learning and fine-tuning of the existing pre-trained network are alternative methods to improve the utilization of the limited data (34).

Other Potential Genetic/Molecular Markers

EGFR is a transmembrane tyrosine kinase that regulates normal cellular growth in epithelial cell lines. The most common EGFR mutant in GB is EGFRvIII, which is found in 31% of patients (76). Using support vector machine–based approaches, Akbari et al. (58) construct an imaging signature of EGFRvIII and achieved an accuracy of 87% in 129 patients with primary GB. The authors also reported that EGFRvIII mutant GB exhibit increased neovascularization and cell density, which is consistent with a more infiltrative phenotype. Zinn and colleagues (52) demonstrated a relationship between MRI radiomics signatures and the TP53-PTEN-EGFR mutational landscape in 29 GB patients from The Cancer Genome Atlas (TCGA). The radiomics features generated by texture analysis revealed different cellular biofunctions, such as angiogenesis, invasion, and immune response. Despite some gaps exist, glioma radiomics landscape is approaching its genomic counterpart in heterogeneity and complexity.

Diffuse midline glioma with histone H3-K27M mutation is a newly defined entity in the WHO group of grade IV diffuse gliomas (77). Those tumors carry a poor prognosis and frequently occur in brainstem, thalamus in the pediatric population. The underlying histological and radiographic variations (78) make it possible to predict the H3-K27M status of a tumor using radiomics analysis. Su and colleagues (48) performed an automated machine learning analysis on MRI data from 100 patients with midline gliomas. After feature selection and model optimization using The Tree-based Pipeline Optimization Tool (TPOT), they finally obtained an AUC of 0.903 and an average precision of 0.911 for the prediction of H3 K27M mutant status in midline glioma. Automated machine learning methods (such as TPOT) are relatively researcher-independent, which increases the robustness of the results.

Signaling Pathways and Biological Processes

Genomic analysis has identified a highly interconnected network of aberrations in GB, including three major pathways: receptor tyrosine kinase (RTK), the retinoblastoma 1 (RB), and tumor protein p53 tumor suppressor pathways (4). Radiogenomics studies have revealed the relationship between different imaging features and certain signaling pathways or biological processes.

In a study of 120 patients with GB, using diffusion, perfusion MRI, and next-generation sequencing technology, Park and colleague (29) combined radiomic and genomic features to predict core signaling pathways in IDH wild-type GB. Different types of radiomic features were identified by the combined radiogenomics model, corresponding to RTK, P53, and RB pathways respectively. This study demonstrates that MRI features can help noninvasively identify the core signaling pathway alterations in GB, which may further support the use of targeted therapy for glioblastoma rather than a one-size-fits-all approach. Another study based on perfusion MRI showed that the elevated perfusion features were significantly associated with poor patient survival in a subgroup of GB patients. Angiogenesis and hypoxia pathways were enriched in this subgroup, suggesting the possible efficacy of anti-angiogenic therapy (79). Similarly, imaging features from enhancing tumor and edematous regions were identified to be associated with the hypoxia pathway (53), imaging markers of hypoxia can discriminate GB patients as short, mid, and long-term survivors.

Radiogenomics studies also highlight sex-related biological variations in GB patients. Colen et al. (80) revealed sex-specific molecular mechanisms for cell death (MYC oncogenic in female GB patients, TP53 apoptotic in male GB patients). Similarly, a recent study by Beig et al. (54) suggested that higher expression of texture features from enhancing tumor regions seemed to be more enriched in 'high-risk' group in the male population. This result appeared to be opposite in the female population, in which the same features were enriched in the 'low-risk' group. These findings suggesting the importance of treating sex as a covariate in the design of a radiogenomics study.

Heterogeneity and Molecular Subtype

Intra-tumoral Heterogeneity in GB has been a topic of long-standing interest (23, 81). Spatio-temporally comprehensive assessment of the tumor heterogeneity requires multiple spatially sampling at different time points. In daily clinical practice, effective tissue sampling remains a significant challenge in accurately evaluating the intratumoral heterogeneity of a GB. Radiogenomics has shown the initial prospects for spatially evaluating the regional and genetically distinct subtypes that coexist within a single GB tumor (30, 82). By collected 48 image-guided biopsies from 13 GBs, Hu et al. (30) co-registered each biopsy location with MRI texture map to correlate spatially matched imaging measurements with regional genetic status. They identified significant imaging correlations for several driver genes, including EGFR, PTEN, RB1, TP53, and more. The author also emphasized that even within one tumor segment (such as the enhancement part in T1 contrast-enhanced MRI), regional genetic diversity can also exist. This suggests the need to improve the image-based assessment of genetic heterogeneity beyond the use of the subregion presented in a single imaging mode.

Images contain information about tumor phenotypes that are regulated not only by cell-intrinsic biological processes but also by the tumor microenvironment (59, 83–85). Recently, machine learning-based radiomics models demonstrated the capacity to evaluate enrichment levels of different immune cells in GB patients. Using radiomics features of MR images, the radiomics models could classify the immunophenotypes of GB and can predict patient prognosis (59). Lin et al. (84) used a consistent clustering method to classify radiological features into two subgroups. The two subtypes have significantly different histological stages and molecular factors (such as IDH and MGMT). Furthermore, biological information analysis hinted that the inferior prognosis subtype may be more responsive to immunotherapy. At the same time, if GB patients receive immunotherapy (such as immune checkpoint blockade therapy), the responses of therapy might also be distinguished by radiomics signatures noninvasively (86). Cho et al. (83) revealed that immune cell markers have significant correlations with perfusion and diffusion MRI features in a study of 60 GB patients. The apparent diffusion coefficient values were correlated with the expression level of immune cell markers, which can be used as an immune biomarker to predict the progression and prognosis of GB patients. It should be noted that many classification methods based on radiomics characteristics are still in an early developmental stage. Although these potential associations are encouraging, some conclusions still need further verification.

Prognostic Stratification-Based Tumor Biological Characteristics

A large number of retrospective studies have revealed the link between the radiomics characteristics and survival time of GB patients (70, 87). According to radiomics risk stratification, some studies (28, 54, 84, 88) also tried to explore the corresponding tumor biological information. Based on survival-related imaging features, some studies (28, 54) construct individualized RRS, by which the patients will be divided into subgroups with different risk stratifications. Further, bioinformatics analysis such as GO and/or GSEA will be used to identify the signaling pathway networks or specific biological characteristics that were associated with RRS features. For example, using data from public platforms, Beig and colleagues (28) extracted 936

3D-radiomics features from T1, T2, and Flair MR images of 203 patients with GB. Finally, the GO and GSEA revealed associations of RRS signatures with signaling pathways for cell adhesion, cell differentiation, and angiogenesis. A somewhat similar approach was followed by Choi et al. (51) who used RRS weighted by Lasso-Cox model to classify patients with GB. Finally, GSEA suggested that the transcriptomic characteristics enriched in personalized subtypes were consistent with radiomics phenotypes. For example, the rim-enhancing necrotic subtype could be described by T2-derived radiomic features and further highlighted by the inflammatory genomic signatures.

Radiogenomics has the potential to unravel the molecular underpinning behind the imaging-derived phenotypes. However, these associations seem to be indirect, since they were constructed through survival variables, such as OS and PFS. Indirect associations may obscure or expand the relationships between radiomics characteristics and molecular phenotypes. In addition to using optimized AI models to integrate all such information, radiogenomics biological validation in animal models (13) would be a promising direction in the future.

Personalized Treatment and Assessment

At present, several studies are exploring combination imaging-genomics with the assessment of early treatment response. Imaging biomarkers have shown great potential to stratify the therapeutic response of patients with recurrent glioblastoma treated with bevacizumab (89). EGFR extracellular domain mutations in GB also present opportunities for imaging and therapeutic development (56). Wei and colleagues (45) used logistic regression to generate a fusion radiomics signature based on conventional MRI of 105 patients with WHO grade II-IV astrocytomas. The fusion signature exhibited great power for predicting the methylation status of MGMT promoter and evaluating temozolomide (TMZ) chemotherapy effect. Petrova et al. (90) collected perfusion and diffusion images from 54 subjects with recurrent GB and subsequently treated with bevacizumab. Among the six different classifiers, the authors found that SVM was able to identify 97% of subjects that would respond to bevacizumab with accuracy for PFS and OS of 82% and 78%. This can help assess whether a GB patient can benefit from anti-angiogenic therapy. However, the model still needs to prove its repeatability and generalizability in an extensive cohort study.

GB is a heterogeneous disease composed of multiple molecular subtypes with different clinical courses, leading to different treatment strategies and prognoses. Radiomics and genomics attempt to explain the diversity of tumors from different perspectives. A more fused model might be used to integrate clinical information and all experimental data of an individual, and propose corresponding molecular networks specific to a personalized GB for efficient early-stage diagnosis, precise treatment recommendations, and prognostic assessment. At present, the underlying transformation of imaging-genomics remains only at an early stage of the investigation. Imaging signatures identified by animal models may be useful for future clinical trials enriched for patients with specific subtypes of GB (13, 86).

FUTURE CHALLENGES

Big Data and Data Sharing

One of the fundamental challenges in imaging-genomics research is the availability of large, standardized, well-annotated data sets. Many studies lacked external testing for evaluating the performance of the models due to the limit of data. While external testing is crucial to confirm model generalizability across different institutions. Data sharing between institutes would bring new opportunities for researchers. The Cancer Imaging Archive (TCIA, https://www.cancerimagingarchive.net/) (91), a part of the Cancer Genome Atlas (TCGA), can provide open-access cancer medical imaging and corresponding genome resources to support imaging-genomics researches (59, 63). Some information about the tumors and corresponding supporting data has been summarized on the TCIA website (https://www.cancerimagingarchive.net/collections/).

Radiological images and biological data from CPTAC (Clinical Proteomic Tumor Analysis Consortium, https://proteomics.cancer.gov/programs/cptac) (92, 93) have also been made publicly available to enable researchers to investigate the imaging phenotypes which may correlate to corresponding genomic, proteomic, and clinical data (28, 54). Additionally, the Ivy Glioblastoma Atlas Project (IvyGAP, http://glioblastoma.alleninstitute.org/) (94) provides resources for exploring the anatomic and genetic basis of GB at the radiological and molecular levels. The dataset contains RNA sequencing data, tissue sections, as well as partial MR data in TCIA. Data from these public databases has motivated and continues to motivate the technological exploration and development in imaging-genomics field. However, such data are far from sufficient. Further researches focused on developing improved algorithms (such as transfer learning or data augmentation technologies) optimized for smaller datasets are also needed.

Quality Control, Interpretability, and Application Challenge

Even for the same data, two different calculation software might generate different feature values (95). The lack of standardized definitions will hamper the clinical use of the models. Undoubtedly, quality control and repeatability should run through the entire imaging genomic study, including data collection, preprocessing, delineation of ROIs, features extraction and selection, model building, and verification. Lambin et al. (10) have proposed the radiomics quality score (RQS) to assess the quality of radiomics studies, which plays a guiding role in improving the initial design of an imaging-genomics research. The Image Biomarker Standardization Initiative (IBSI) also produced and validated a series of consensus-based reference values for radiomics features (95). These reference values can be used to check whether a radiomics software complies with IBSI standards. Improved research quality and reproducibility can promote the clinical translation of radiomics.

In the clinical setting, there are still many obstacles to the standardized processing of data and the effective deployment of the pre-trained models. The lack of sufficient verification of a model will inevitably limit its further application. Additionally, it is also important to note that features and models generated by AI (especially deep learning) often lack clear interpretable parameters. Even if AI algorithms provide good predictive results, the models and deep features are difficult for clinicians to interpret, which limits the integration of radiomics into routine clinical practice. In the context of a regulated healthcare environment, this "black box" problem of AI algorithms is particularly outstanding. Visualization of models and features is an alternative way to alleviate this problem. Interpretability in AI is an emerging field of increased research efforts in the data science community.

Multi-Omics Integration

Multi-omics is undergoing the big data revolution. Genomic analysis such as gene mutation or altered gene expression alone does not always reflect the real change of the corresponding protein and downstream metabolite. The intricate connections between tumor biology and holistic phenotype could have been better captured by multidimensional data and multi-omics models. In recent years, leveraging AI and digital pathology has shown significant promise in cancer diagnosis (38, 49). Remarkably, there have been attempts to integrate pathological section data and radiological data (96), which is called a new term as radopathomics. The fusion signature combining information from distinct dimensions could better predict discrepancies of treatment response. These results have exhibited the great potential of radiomics in the integration of modern precision medicine.

Predictably, the evolution of the radiomics field will gradually differentiate into "radio-…omics", such as radio-proteomics, radiopatho-genomic, or even radio-metabonomics in the coming future, dependent on the source used. As such, current imaging-genomic association maps entail integrations of large, "multi-omic" data sets with imaging to bridge the missing links. Certainly, such a large number of omics features can easily lead to overfitting. Optimal feature reduction and selection methods and appropriate model validation are also needed to deal with the problem of "Curse of Dimensionality".

CONCLUSION

The evolution of the field of radiomics and radiogenomics is similar to the emergence of the microscope in pathology. It is foreseeable that based on multi-parameter imaging features, more biological information can be mined to evaluate the biological characteristics of GB for supporting individualized patients management. However, many challenges still exist and much work needs to be done. Better interpretability and validation of these tools will make imaging genomics more acceptable in this field. Even though the translation of these models from research to clinical practice is still in progress, they provide promise for guiding precision medicine and subsequent individualized therapeutic intervention.

AUTHOR CONTRIBUTIONS

HL and WZ conceived this review, organized, and critically revised the manuscript. DL and JC did major work of the manuscript. XH, KY, YL, GH, and HG made contributions to the writing and revising of the manuscript. All authors contributed to the article and approved the submitted version.

FUNDING

This study was supported by grants from the National Natural Science Foundation of China (No. 81972350, 81701671), the project of Jiangsu Provincial Medical Youth Talent (No. QNRC2016047), the Medical Scientific and Technologic Development Project of Nanjing (No. ZKX15035), the Jiangsu Provincial Medical Innovation Team (No. CXTDA2017050), the Medical Science and Technology Development Foundation of Nanjing (No. ZDX16011), and the Nanjing Medical Science and technique Development Foundation (No. QRX17087).

Abstract

The post-genomic era of functional genomics and target validation will allow us to narrow the bridge between clinically correlative data and causative data for complex diseases, such as arthritis, for which the etiological agent remains elusive. The availability of human and other annotated genome sequences, and parallel developments of new technologies that allow analysis of minute amounts of human and animal cells (peripheral blood cells and infiltrating cells) and tissues (synovium and cartilage) under different pathophysiological conditions, has facilitated high-throughput gene mining approaches that can generate vast amounts of clinically correlative data. Characterizing some of the correlative/causative genes will require reverting to the hypothesis-driven, low throughput method of complementary experimental biology using genomic approaches as a tool. This will include *in silico* gene expression arrays, genome-wide scans, comparative genomics using various animal models (such as rodents and zebrafish), bioinformatics and a team of well trained translational scientists and physicians.

For the first time, the 'genomic tools' will allow us to analyze small amounts of surgical samples (such as needle biopsies) and clinical samples in the context of the whole genome. Preliminary genomic analysis in osteoarthritis has already resurrected the debate on the semantic issues in the definition of inflammation. Further analyses will not only facilitate the development of unbiased hypotheses at the molecular level, but also assist us in the identification and characterization of novel targets and disease markers for pharmacological intervention, gene therapy, and diagnosis.

1. Genetic Complexity and Arthritis

Arthritis is a complex disease with an unknown etiology. Based on the clinical symptoms, it can be classified as osteoarthritis (OA), rheumatoid arthritis (RA), synovial lipomatosis, avascular necrosis, crystal deposition disease, gout, and other minor diseases. The common underlining symptoms in the above clinical manifestations include destruction of joints and inflammation.[1]

Unlike arthritis, monogenetic diseases (e.g. cystic fibrosis) have been identified where one single mutation is responsible for the dysfunction of the gene leading to the disease. It took several years to map and characterize the gene responsible for cystic fibrosis.[2] The development of new genomic approaches and tools has facilitated the identification of over 40 new genes known to be involved in various diseases in the last 3 years,[3] which are mostly the low hanging fruits of this vast sea of information. The major challenge faced is characterization of genes involved in oligo- and polygenic disorders such as arthritis, because pedigrees from complex diseases reveal no Mendelian inheritance patterns, and single gene mutations are neither sufficient nor necessary to explain the disease phenotypes.

Many traits of either the normal or diseased state in humans are controlled by a single gene and, thus, have a distinct, discontinuous, phenotype (e.g. blood type). There are other traits where a continuous distribution is observed in a segregating population (e.g. weight gain, IQ, learning ability, etc.), yielding a bell-shaped curve when analyzed quantitatively. Thus, continuous traits are often given a quantitative value, referred to as quantitative trait. Furthermore, the genetic loci controlling these traits are called the quantitative trait loci (QTL). Mapping markers linked to QTL helps identify regions of the genome that may contain genes involved in the expression of the quantitative trait.

QTL are generally regulated by several genes.[4] This is not a rule of thumb because in non-animal species positional cloning of a QTL revealed that a single gene was responsible for the complex regulation of tomato fruit size.[5] It is possible that some of the human QTL may also prove to have a single gene responsible for complex disorders. A preliminary map of QTL in mice has recently been published, which may facilitate structure-functional analysis of similar genes in humans.[6-9] Human arthritis may involve several genes and gene products influenced by physical, environmental, and other risk factors. Furthermore, QTL have been identified for arthritis in rat models (e.g. *Cia5*, *Cia7*, *Aia3/Cia3*, etc.).[10-13] The possibility of QTL being involved in human arthritis cannot be discounted.

Advances in various molecular biology tools and information in genomics now permit the detailed study of complex diseases such as arthritis, for example, the etiology and the pathogenesis of joint destruction. The greatly enhanced flow of information provides us with an opportunity to reassess our working hypothesis. Such a reassessment allows us to unravel the physical or biological basis of the mysteries of complex diseases.

2. Gene Mining in Arthritis

Basically, there are two approaches to gene mining in complex diseases that have been used in arthritis and inflammatory diseases. The first approach is to compare gene expression arrays of normal and diseased target tissues. The second approach for gene mining is using genome-wide scans, association studies and positional cloning analysis utilizing microsatellite marker loci, sibling pairs and disease-susceptible families.

2.1 Gene Expression Analyses

Good examples of target tissues for analysis of differential gene expression in arthritis are cartilage, synovium, and blood leukocytes. Figure 1 shows an approach using complementary technologies for human cartilage. We[14,15] and others[16-19] have applied some of these strategies. Differential gene expression using subtractive hybridization of synovium for RA and OA has also been examined.[20,21]

It is estimated that 10 000–20 000 transcripts and 50 000–80 000 proteins are expressed in a given cell at a certain time period. Therefore, the gene mining technologies described in figure 1, either individually or in combination, have the tendency to generate an enormous number of differentially expressed transcripts, expressed sequence tags (ESTs) and proteins, which may be involved (either directly or indirectly) in the disease process. These potential targets have to be reduced to a manageable number by prioritizing the ones that may be involved in the disease process. Prioritization can be based on criteria such as tissue and/or cell specificity, and relative abundance (see Attur et al.[23] for a recent review). Computational data analysis and clustering algorithms can be optimized for each project to extract relevant information. Another strategy to reduce targets to a manageable number would be to apply pharmacogenomic screens (*in vitro* and *in vivo*), and to compare the targets to chemogenomic databases during pharmacological intervention using various reagents/drugs such as anti-tumor necrosis factor-α (TNFα) and/or recombinant TNF antagonists.[24]

2.2 Genome-Wide Scans, Association Studies, and Positional Cloning

Genome-wide scans provide the means to identify several trait-related genetic factors. In this approach, a large collection of genetic markers is tested for association with the disease. These markers are distributed frequently enough across the chromosomes so as to cover the whole genome. By themselves, they may or may not be related to the diseased state, however, their proximity to a susceptibility gene may reflect their effect on the gene.

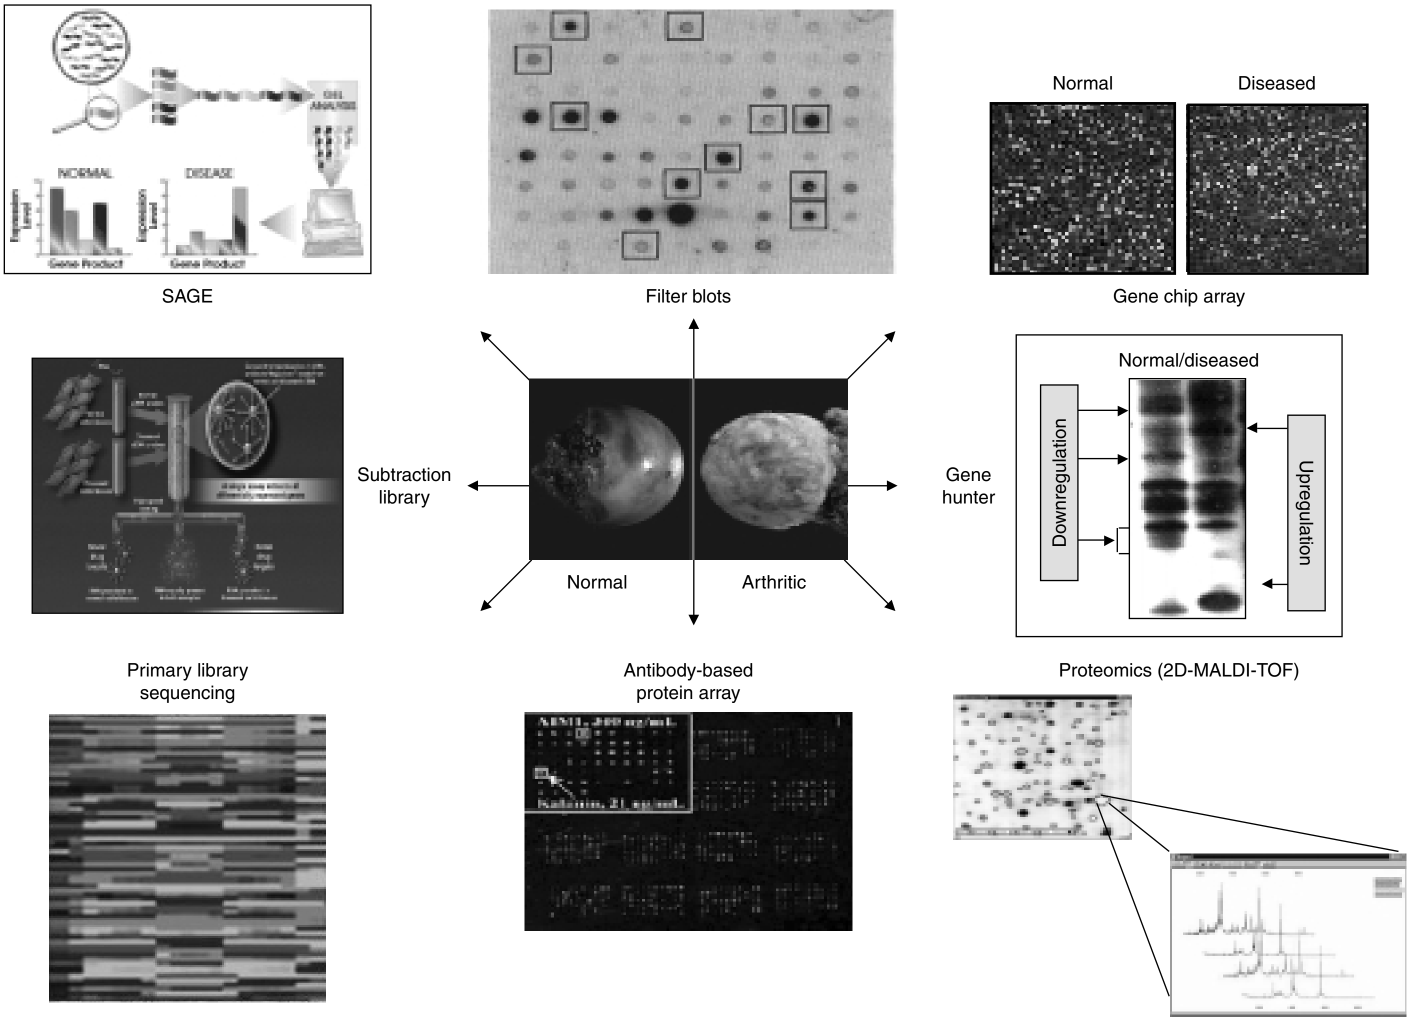

Fig. 1. Gene mining in human cartilage. There are several methods of gene mining in cartilage and differential expression of genes/proteins in normal and arthritis-affected cartilage. Total RNA and protein can be extracted from human cartilage and subjected to various analyses. These include oligonucleotide-based gene chip arrays on glass and filter membranes, differential display of arbitrary nested primers (Gene Hunter Kits, Gene Hunter Corp., Nashville, TN, USA), proteomics with two-dimensional matrix-assisted laser desorption time-of-flight (2D-MALDI-TOF), antibody based protein arrays, high-throughput DNA sequencing of primary cDNA libraries and substraction libraries, preparation of cDNA libraries for Serial Analysis of Gene Expression (SAGE) and radiolabeled dot (filter) blots. These technologies on the whole, cover a broad area of gene mining and complement each other.[22]

Examination of the outcomes of such multiple testing processes may potentially uncover regions in the genome containing a gene (or genes) associated with the trait.

Positional cloning of genes based on their position on the genomic map is a method of choice for isolating genes for which only a mutant phenotype is known. Many genetic disorders result from mutations in genes whose phenotype (or protein product) and/or function is unknown. Several genes have been identified using this approach, one of the earlier ones being the X-linked gene for chronic granulomatous disease in 1996. Other examples include the *IBD5* gene for Crohn's disease, and genes associated with Huntington disease, cystic fibrosis, and obesity.[25]

Recently, large cohort genotypic studies suggested that the susceptibility genes for human OA and RA have been mapped on chromosome 16p between 28cM and 47cM from the telomere at 1(D1S235), 4(D4S1647), 12(D12S373), 16(D16S403 and D16S401), 17(D17S1301), 10(D10S2327 and D10S201), 14(D14S587 and D14S285), which overlap with other autoimmune and inflammatory diseases.[26,27]

3. Validating Target Hypothesis

Target validation serves as an important bridge between correlative data and causative data. Figure 2 summarizes the methods to generate hypothesis-driven correlative data and validation of these against causative data sets. The ultimate biological validation of a pharmaceutical target comes with the successful phase III clinical trial and broad application of the therapy to a large population of patients.

Fig. 2. Approaches to bridge correlative data with validation and causative data. There are a number of methods to accumulate correlative data, as shown in figure 1. Potential targets developed using various screening methods require a specialized approach to validate or exclude them as causative targets before they can be ultimately validated in humans through clinical trials. Bioinformatics plays an essential role in bridging the two areas. **EST** = expressed sequence tag; **SAGE** = Serial Analysis of Gene Expression.

Here we focus on correlating the target hypothesis to the disease under study using various examples in arthritis. Validation procedures have become an important component of gene mining studies because of the following difficulties: (i) much of these gene mining technologies have not been compared in parallel with one another using the same clinical samples; (ii) some of the commercially available gene chips had serious flaws in probe design and reproducibility, as evidenced recently;[28] (iii) the new generation of commercial chips (with increasing probe sets such as U133A from Affymetrix Corporation, CA, USA) and the updated microarray data analysis software are not compatible with the previous generation of chips (e.g. U95); (iv) some of the low abundant and short half-life transcripts (e.g. membrane proteins and some cytokines) are not detected in clinical samples when using these gene chip arrays; and (v) variation in the read-outs (^{32}P or fluorescent labeled probes, pseudo-colors or semi-quantitative methods). All of these shortfalls impede cross-sectional statistical analysis for target validation. There are some reports which address these issues.[29-32]

Real-time PCR has been a method of choice for validating differentially expressed transcripts.[33,34] We have successfully identified and validated low abundance transcripts (5–100 copies of mRNA) involved in inflammation that were missed in gene chip arrays.[34] Subcellular localization of differentially-expressed targets by *in situ* staining using antibodies or riboprobes is important. This has recently been demonstrated using differentially expressed target genes such as *SPP1* (secreted phosphoprotein-1 or osteopontin), *EGR1* (early growth response-1), and matrix metalloproteinase genes *MMP1*, *-3*, *-8*, *-9* and *-13* in arthritis.[35,36] Gene expression patterns of *MMP1*, *MMP3* and *MMP9* in OA-affected cartilage were found to be zonal and grade-specific.[37] These approaches can allow validation of targets across sections of clinical samples.

4. Functional Genomics

Functional genomic analysis involves a systematic effort to understand the function of genes and gene products and biological systems classically performed for single genes in the context of the whole genome. Functional genomics can be conceptually divided into two approaches:

1. the gene-driven approach, where one uses genomic information for identifying, cloning, expressing, and characterizing the gene at the molecular level
2. the phenotype-driven approach, which analyzes phenotypes from random mutation screens or naturally occurring variants (mouse mutants, human diseases) to identify and characterize genes associated with the phenotype, without prior knowledge of the underlying molecular mechanism or function.

These strategies are complimentary, leading collectively to association of phenotypes with genotypes. As functional genomics begins to mature into a coherent science (as molecular biology did in the last half of last century) its constituent fields become clearer. As shown in figure 3, they include bioinformatics, structural genomics, comparative genomics, expression genomics, and proteomics. The use of these fields in studying arthritis, with emphasis on genes encoding MMPs, matrix proteins/proteoglycans, cytokines and cytokine receptors, are discussed in section 4.3.

4.1 Cell Culture Systems

Several different cell culture systems have also been used for functional analysis in cartilage and chondrocytes. Primary chondrocytes (outside the cartilage) have a tendency to dedifferentiate in *in vitro* systems. However, recent studies by Goldring et al.,[38] have shown immortalization of human chondrocytes using retroviral vectors expressing SV40-large T antigen, to maintain the chondrocyte phenotype without dedifferentiating into fibroblast-like cells. These cells, although they lack several important phenotypic characters of a chondrocyte such as the production of nitric oxide (NO) and prostaglandin E_2 (PGE_2), have proven to be useful for studying a variety of general and chondrocyte specific functions.

An approach to restore the differentiated properties of chondrocytes is by cultivating them in alginate beads, alginate-fibrin carrier, or other scaffolds for cartilage/chondrocyte culture sys-

© 2004 Adis Data Information BV. All rights reserved.

tems.[39-41] This system supports cell proliferation without the loss of functional potential. Furthermore, the cells can be retrieved for analysis by dissolving monomer subunits using chelating agents. Another approach is to grow primary chondrocytes in collagen II coated dishes, allowing the chondrocytes to wrap around their own matrix and maintaining the chondrocyte-like phenotype.[42] Alternatively, chondrosarcoma cells, which retain much of the chondrocyte phenotype, can also be used for functional analysis.[43] Immortalized human synovial cells have also been used for similar studies.[44] However, the choice of chondrocyte culture system for *in vitro* studies for pharmacological intervention should be chosen keeping in mind the expected goals or questions asked.

4.2 Functional Genomics in Animal Models

Animal models of arthritis are somewhat self-limiting because they aim to reproduce a human disease phenotype that is heterogeneous in nature. There are no clear-cut genetic models of arthritis (OA or RA) as the etiological gene(s) under specific genetic background are elusive. At least three examples can be cited for this.

1. Mutations in camptodactyly-arthropathy-coxa vara-pericarditis (CACP) or lubricin or proteoglycan 4 (PRG4) in humans show flexion contractures of all fingers and bilateral swelling to destruction of joints.[45] Marcelino et al.[46] developed homozygous knockout mice for CACP. This mouse showed hyperplasia of synviocytes and increased matrix deposition in the subintimal layer. These studies show similar phenotypic characteristics in humans and mice with similar genotypioc defects.[45]
2. Mutation in *COL10A1* leads to Schmid metaphyseal chondrodysplasia (SMCD) in humans. Recent studies by Chan et al.[47] in mice showed mutation in a single allele of *COL10A1* (haploinsufficiency) also demonstrated SMCD similar to humans. These studies suggest the importance of gene dosage *per se* in animal models of arthritis.
3. Mutation in the MMP2 gene in humans causes multicentric osteolysis and arthritis syndrome[48] whereas the MMP2 null mice

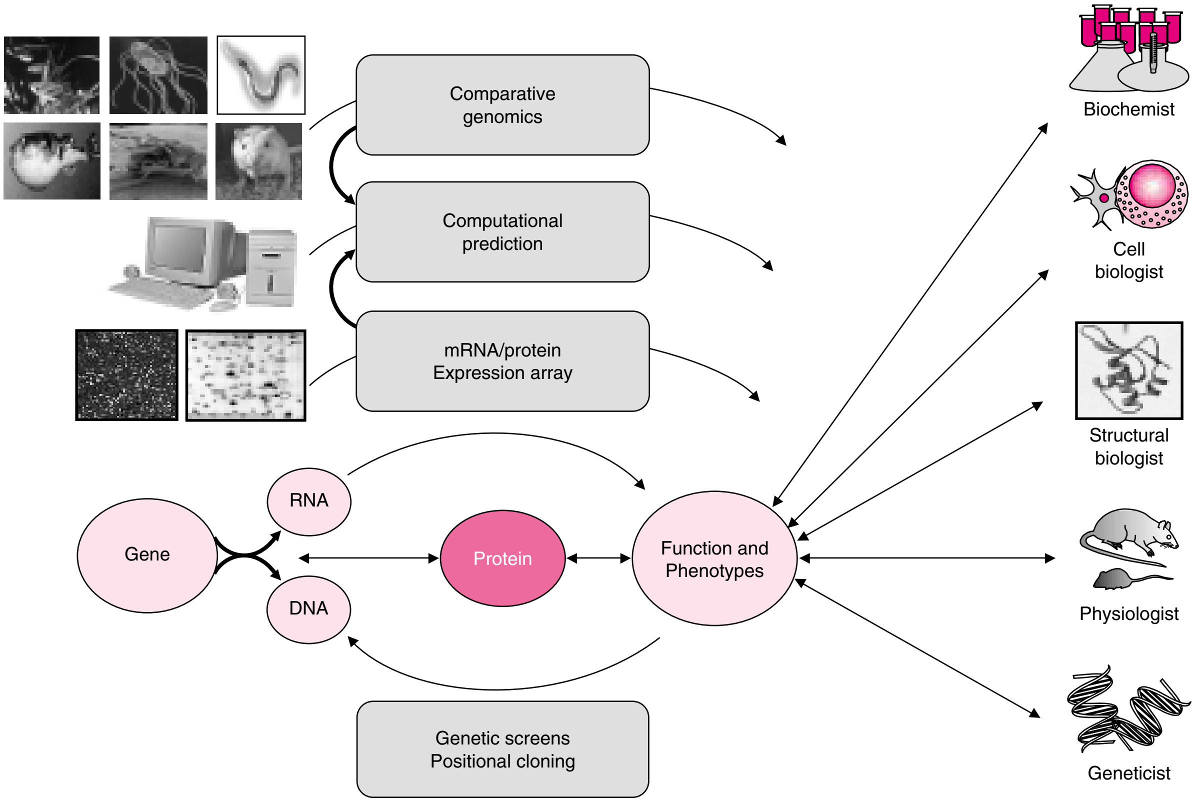

Fig. 3. A matrix approach to functional genomics. A global multidimensional integrated program is required with respect to tools, technology, and training of individuals in various areas of biological sciences to fully exploit the power of functional genomics in medicine. The present gene-mining approaches can identify target genes and/or biomarkers outside the area of expertise of the investigator and, hence, require adaptation for crossing over to other fields. Gene expression arrays and proteomics remain important tools to develop working hypotheses and also validating targets. Computational predictions facilitate hypothesis-driven prediction, clustering analysis and preparation of databases for future references. Bioinformatics also bridges analysis between comparative genomics and expression arrays (mRNA/protein) for functional genomics. Comparative genomics using relatively simple genome structure of microbes, nematodes, arthropods, Zebrafish, puffer fish, mice, and other lower vertebrates, becomes a key in dissecting and validating targets for complex human diseases. These strategies bridge and complement the gene-driven approaches and phenotype-driven approaches in diseased individuals, animal models or dysfunctional cell types to identify and validate targets.

© 2004 Adis Data Information BV. All rights reserved.

developed normally, except that there is a subtle delay in their growth. However, MT1-MMP (membrane type MMP1; MMP14) null mice showed a phenotype similar to osteolysis patients even though both MMPs are implicated in the pathophysiological process in arthritis in humans. It should be noted that MMP14 is a regulator of MMP2. These studies suggest that similar phenotypes are observed in humans and mice with closely regulated or related MMPs.

Therefore, multiple approaches may be necessary for target validation. Furthermore, genes that have not previously been implicated in OA, have been identified using this approach.[23] There are no fixed criteria to select a target for such mouse models and it all depends on the question one is asking.

4.2.1 Development of Autoimmune Transgenic Mice for Rheumatoid Arthritis

Joint degradation characteristic of RA is a result of an autoimmune response. Various genomic technologies have facilitated the identification of novel auto-antigens that may play a role in arthritis. These can be functionally examined by using transgenic animals. A transgenic mouse (K/BxN T cell receptor [TCR]) spontaneously develops a joint disorder with many of the clinical, histological, and immunological features of human RA.[49] The disease is initiated by a subset of T cells recognizing a self antigen identified as glucose-6-phosphate isomerase, a glycolytic enzyme. Thus some forms of RA or related arthritis may be developed by a mechanism fundamentally different from the current paradigm of joint-specific T cell response.

4.2.2 An In Vivo Model of SCID Mouse for Human Cartilage Invasion

Synovial hypertrophy and pannus formation play a critical role in inflammation and cartilage destruction in RA. In view of this, Jorgensen and Gay[50] have developed a human synovial fibroblast/cartilage interaction model *in vivo* to examine the role of various genes. This model allows examination of synovial cell activation, attachment to cartilage and its role (and mechanism) in destruction of cartilage. Briefly, human RA-affected synovial fibroblasts are grown *in vitro* and transfected with a gene of choice using a retroviral vector. The cells are then packaged in an inert sponge together with normal human cartilage and implanted in a renal capsule in severe-combined immunodeficient (SCID) mice, which do not evoke an immune response to the transplantation. The gene expression is mostly stable for 60–80 days, during which time various forms of bioassays and analyses can be performed.[50] This strategy has been utilized to examine the effect of interleukin (IL)-1 receptor antagonist (IL-1Ra), TNF receptor I (TNFRI), IL-10, tumor suppressors PTEN (phosphatase and tensin homolog) and p53 in cartilage degradation.[24,51,52]

4.2.3 Genetic Disorders in Human Cartilage/Skeleton

The cartilage extracellular matrix is composed of numerous macromolecules. The major constituent is collagen fibrils composed mainly of type II collagen which in turn interacts with various proteins, which include peptidoglycan and aggrecans. Recently several studies have shown that loss of cartilage matrix protein such as collagen has drastic effect on skeletal development. The mouse mutant for both extracellular matrix (ECMs) proteins showed severe and lethal chondrodysplasia.[53-55] Recently Mier et al.[56] have also shown that mutations in type II precollagen gene in children results in precocious osteoarthritis. Conversely, Baldwin et al.[57] have shown that there is no linkage or association between type II collagen mutation and osteoarthritis.

Chondrocytes express collagen type II, V, VI, IX, X, XII, and XIV, depending on their physiological stage.[58] Approximately 278 different mutations have been reported to date in genes for type I, II, III, IX, X, and XI collagens in various diseases which impact bone, cartilage, and blood vessels. A majority (78%) of the mutations are single-base changes either alter the codon of a critical amino acid or lead to abnormal RNA splicing, which may lead to a spectrum of diseases of bone and cartilage including osteogenesis imperfecta (a type of chondrodysplasia) and OA.[59] Some of the phenotypes of these mutations have been examined in mouse models.

Collagen type IX is a non-fibrillar collagen localized on the surface of type II collagen. Alternatively spliced forms of collagen type IX are expressed on hyaline cartilage and other tissues. A mouse strain lacking both forms showed no detectable abnormalities at birth, but developed a severe degenerative joint disease resembling human OA.[60] Similar experiments by Nakata et al.[61] using a tissue-specific promoter/enhancer to express type IX collagen revealed pathological changes similar to human OA and chondrodysplasia.

The interaction between different collagens plays an important role in cartilage homeostasis. Although mice deficient in collagen II (Col2a1−/−) die at birth, and Col9a1−/−develop OA-like phenotypes, the Col2a1+/−Col9a1−/−mice show no accelerated OA.[62] These observations suggest that extracellular matrix proteins have different roles during cartilage development. Type II collagen may be important for cartilage formation, and type IX collagen may be required for cartilage maintenance.

4.2.4 Other Animal Models

Zebrafish serve as a powerful experimental model for functional genomics in identification of developmentally important genes that can be related to human development and disease.[63] In zebrafish, the cartilage of the pharynx develops during late embryogenesis and grows extensively in the larva before eventually being replaced by bone. The detectable expression of genes both during development as well as in the adult, and the potential for studying gene interactions and over-expression all suggest that this

© 2004 Adis Data Information BV. All rights reserved.

model system would contribute substantially to the understanding of this complex system of cartilage and bone development.

4.3 Molecular Targets in Arthritis

4.3.1 Matrix Metalloproteases (MMPs)

Matrix metalloproteases, also called matrixins, play major roles in extracellular matrix turnover. Dysfunctional expression of MMP activity constitutes part of the pathogenic mechanism associated with a wide range of diseases. These include tissue breakdown and remodeling during invasive tumor growth and tumor angiogenesis,[64] degradation of myelin-basic protein in neuroinflammatory diseases,[65] blood-brain barrier following brain injury,[66] increased matrix turnover in atherosclerotic plaques,[67] loss of aortic wall strength in aneurysms,[68] tissue degradation in gastric ulceration,[69] and liver fibrosis.[70] MMP expression has been extensively studied in OA and RA. The expression of MMPs (MMP-1, -3, -9 and -13) in arthritis is strongly stimulated by inflammatory cytokines such as IL-1 and tumor necrosis factor-α (TNFα).[37,71]

MMPs belong to a superfamily of zinc-dependent proteases known as metzincins. Based on sequence and structural similarities, metzincins are grouped into four distinct subfamilies: the astacins, matrixins (MMPs), the adamalysins (or snake venom proteases and ADAMs), and the seralysins (large bacterial proteinases). The term ADAMs stands for *a d*isintegrin and *m*etalloprotease, which represent the two key structural domains in these molecules. ADAMs are distinct among cell surface proteins in containing features of both adhesive proteins and proteinases, and their roles in cell-cell interactions have attracted particular interest in recent times.

Recently, new members of the ADAM family, known as ADAMTS (*ad*isintegrin *a*nd *m*etalloprotease with thrombospondin motifs), have been characterized, which include aggreganase (ADAMTS-4 and -5).[72] The ADAMTS are also distinguished from the ADAMs by their lack of cysteine rich, endothelial growth factor (EGF)-like, transmembrane, and cytoplasmic domains. The structure/function relationships of various MMPs (ADAMs and ADAMTS) are elegantly reviewed elsewhere.[73,74] MMP activity is also regulated by endogenous inhibitory activity, attributed to a family of four tissue inhibitors of metalloproteases (TIMPs). TIMPs act by forming a 1 : 1 complex with the activated catalytic zinc-binding domain in the MMPs. Chronic stimulation of MMP activities due to an imbalance in the levels of MMPs and TIMPs has also been implicated in the pathogenesis of variety of diseases such as cancer, OA and RA.[75]

Among the 25 vertebrate MMPs identified to date, 22 human homologs have been confirmed.[76,77] Each of these MMPs has distinct as well as overlapping substrate specificities, and can virtually cleave most ECM proteins involved in joint destruction in RA and OA. These enzymes are predominantly produced by macrophages and neutrophils in the synovial pannus in RA, and cartilage in OA.

Differential Expression and Identification of Proteases from Human Arthritis-Affected Cartilage

Adamalysin (ADAM) Proteases

The analysis of the human genome has allowed us to predict the presence of approximately 500 MMP-like transcripts in humans, which have yet to be functionally characterized.[78,79] Human arthritis-affected cartilage and synovium are one of the richest sources of differentially expressed disease-specific proteases.[14,36,37] We, and others, have therefore selected healthy and diseased cartilage to identify novel proteases. Gene mining efforts using total RNA from healthy, RA- and OA-affected cartilage,[14] yielded a clone (clone 8) that was up-regulated and showed two important characteristics in its partial cDNA sequence. The first is a partial cysteine switch sequence (PKVGY) and zinc binding region (HELGHN), revealed by comparative genomics as being similar to that seen in snake venom proteases.[80] Secondly, the distance between the two motifs was found to be approximately 690 base pairs. This was classified as a unique protease because these characteristics excluded the matrixin family of MMPs.

Since the sequence homology was not sufficient to predict the nature of the clone, comparative genomics and bioinformatic approaches were further combined to compare the 3-D ribbon structures of clone 8 to the catalytic region of other MMPs across species, including snake venom proteases. In spite of the low sequence homology, the three hydrophobic side chains that support 3-D folds were conserved in snake venom protease and clone 8 (figure 4), suggesting that clone 8 peptidase was structurally and functionally similar to M12B snake venom protease family. The full-length cDNA sequence of these cartilage snake venom proteases (atrolysin [C/D] and adamalysin) [figure 4] showed approximately 99% homology to TNFα convertase (TACE).[14] Although the overall sequence identity was not very high, the alignment score (20.4 for liag, which represents the protein database code for a three-dimensional structure of adamylasin II, solved at 2.0A resolution) suggested similarity between sequences of adamalysins and the clone 8[81] that was several sigmas above the noise level.

TACE is a potential target for pharmacological intervention of TNFα production, based on its ability to cleave membrane-bound proTNFα from soluble TNFα. Other putative substrates for TACE include L-selectin, TNFα receptors I and II, amyloid precursor protein (APP), IL-1 receptor and IL-6 receptor.[82]

How does TACE distinguish between all of these substrates? Preliminary data suggests that different domains of TACE are necessary for turnover of different substrates.[82] Inhibitors of TACE block TNFα activity in arthritis-affected cartilage.[83] These experiments demonstrated a functional paracrine/autocrine role of

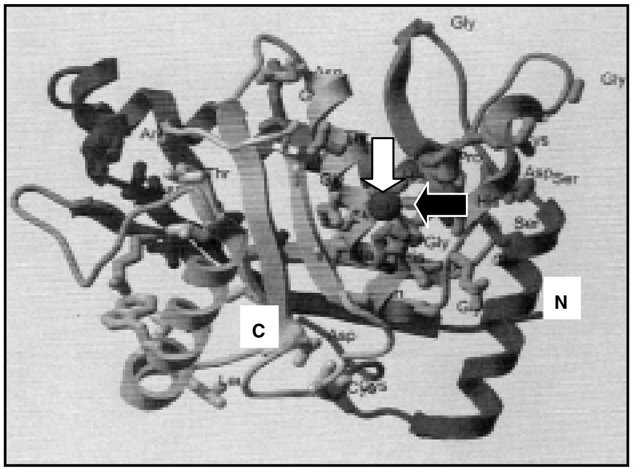

Fig. 4. Superimposition and comparison of the catalytic metallopeptidase region of atrolysin (C/D)/adamalysin with Clone 8. Human osteoarthritis (OA) and rheumatoid arthritis (RA)-affected cartilage when compared to normal cartilage showed upregulation of a partial transcript which was identified as Clone 8. The 3-dimensional structure of atrolysin (C/D)/adamalysin was used as a template. Only the residues conserved between atrolysin, adamalysin, and Clone 8 are shown by balls-and-sticks. Three conserved catalytic histidines are shown with a darkened arrow. Zinc ion is shown with an open arrow. The ribbon is marked as N to C terminus. The molecular modeling showed structural similarities in spite of low sequence homology (reproduced from Amin,[22] with permission).

TNFα in arthritis-affected cartilage that may depend, in part, on up-regulated levels of chondrocyte-derived TACE.[14] Furthermore, such *ex vivo* functional genomic assays provide real-time TNFα and TACE expression data in cartilage. Mice lacking active TACE have been generated and characterized. Although cells from TACE deficient mice release 80–90% less soluble TNFα than wild type cells, mice lacking TACE results in perinatal lethality.[84]

Serine Proteases

Hu et al.[16] utilized a known differential gene expression approach using a Gene Hunter kit (GenHunter Corp., Nashville, TN, USA), to characterize the function of a differentially expressed protease in OA-affected cartilage. This technique amplifies a family of proteases with specific domains and may exclude other important proteases. This approach picks up novel transcripts but it is labor-intensive and produces a sizable number of false positives.

Differential expression of transcripts in healthy and OA-affected human cartilage identified an evolutionarily conserved serine protease, the human high-temperature requirement A (HtrA, gene name *PRSS11*), which was up-regulated (7-fold) in human OA-affected cartilage compared with healthy cartilage.[16] Cloning and expression of *PRSS1* revealed endoproteolytic activity, including autocatalytic cleavage. The putative active site was mapped to serine 328. Recent substrate specificity studies suggest that this protease has the ability to degrade cartilage oligomeric matrix protein (COMP) and fibronectin, which are major structural proteins found in human cartilage.[85]

Identifying the Role of MMPs by a Phenotype-Driven Functional Genomic Approach

Familial osteolysis is a rare inherited disorder in which affected individuals exhibit characteristic facial features, lytic lesions of the bone, and arthritis. Linkage analysis showed *MMP2* as a candidate gene harboring a mutation in four Saudi Arabian families.[48] *MMP2*-null mice have no developmental defect, which may reflect genetic redundancy. However, it should be noted that mice with the *MMP14* gene defect have many of the same features as individuals with osteolysis and arthritis. One explanation of the difference between humans and rodent may be due to distinct regulation of *MMP2* and *MMP14*, and the balanced regulations they exert on inactive and active transforming growth factor-β (TGFβ).[86] Overexpression of TGFβ causes deregulation of bone remodeling, where as inhibition of TGFβ signaling results in cartilage destruction resembling OA.[87] This example highlights the limitation of mouse gene targeting methods despite their exquisite potential for addressing gene functions in defined contexts. This is an excellent phenotype-driven functional genomic approach wherein a defined phenotype is correlated from rodents to humans. However the drawback of this approach lies in the requirement of a pure family of familial genotype, which can be correlated to the observed phenotype.

4.3.2 Extracellular Matrix Components

Functional Genomic Analysis of Differentially Expressed Matrix Components in Cartilage

In tissues like bone and cartilage, ECM components regulate some of the most fundamental cellular processes such as growth, survival, differentiation, motility, signal transduction, and cell shape.[15,88,89] A close look at chondrocytes in cartilage by electron microscopy show that these cells are relatively larger in size than other inflammatory cells such as macrophages (~25μm vs 3.8μm in diameter and are metabolically active).[33] Furthermore, the chondrocyte cell membrane is highly invaginated (similar to microvillae) into the pericellular region of the matrix. Several types of surface receptors on chondrocytes have the ability to bind to various types of ligands in the matrix.[90] These include collagen, proteoglycans, COMP, osteopontin, and vitronectin.

Examination of the role of matrix proteins in human cartilage requires an unconventional assay system. We have developed an *ex vivo* organ culture assay to examine the role of chondrocyte/matrix interaction in cartilage without disturbing its delicate architecture (figure 5).[91] These arthritis-affected cartilage samples spontaneously release various inflammatory mediators, including NO, PGE_2, MMPs, cytokines which modulate matrix homeostasis in *ex vivo* culture.[89] Recombinant proteins such as ligands, soluble receptors, antibodies, and low molecular weight disease-modi-

fying antirheumatic drugs (DMARDS), can be added to the assay to analyze inflammation and cartilage homeostasis. This approach has recently been extended into pharmaco- and chemogenomic assays for profiling transcripts in the presence of NSAIDS and DMARDS, which have the ability to modify homeostasis in cartilage.[92-94] This type of assay not only facilitates understanding functional genomics of potential targets but also the validation of targets in the human system as described in figure 5.

Fig. 5. Human arthritis-affected cartilage *ex vivo* assay for functional genomics and pharmacogenomics. Human cartilage organ culture was conducted as described previously.[34] Briefly, knee articular cartilage from patients undergoing knee replacement surgery was obtained and cut into 3mm discs, and 4–6 discs (~100mg) were placed in organ culture in 2mL of Ham's F-12 medium and 0.1% human albumin for 24–72h with or without modulators (recombinant proteins, neutralizing antibodies, small molecule drugs). The medium was analyzed for soluble mediators such as prostaglandin E_2 (PGE_2), nitric oxide, cytokines, and chemokines. RNA was isolated from the cartilage at time zero and different timepoints and utilized for pharmacogenomic analyses such as gene expression arrays. **DMARDs** = disease-modifiying antirheumatic drugs.

Functional Analysis of Osteopontin in Cartilage

Osteopontin (OPN) is a phosphorylated glycoprotein secreted by activated macrophages, T-cell leukocytes and bone derived cells. OPN is present in extracellular fluids at the site of inflammation matrix of mineralized tissues. OPN mediates important cell-cell interactions and cell-matrix interaction through engagement of receptors including integrins $\alpha_5\beta_3$ and CD44 (hyaluronic acid receptor).[95,96] Differential expression of mRNA in normal and arthritis-affected cartilage showed up-regulation (300–700%) of fibronectin and osteopontin.[15,97]

Independently, genetic associations of nodal OA with two loci on chromosome 2q were identified using microsatellite marker loci and sibling pairs. One of the candidate genes in this region was the fibronectin gene (*FN1*), a potential target ECM gene for therapy identified by both differential mRNA expression and conventional population based genetic approaches.[98] Furthermore, Saito et al.[99] have also shown that fragments of fibronectin protein are functionally active as they up-regulate inflammatory mediators in human chondrocytes and other inflammatory cells.

Based on these observations, subsequent studies were focused on the identification of function of osteopontin in OA-affected cartilage. The effect of recombinant osteopontin (or affinity purified anti-osteopontin serum) on chondrocyte function in cartilage was examined. Human recombinant osteopontin at 1 μg/mL (20 nmol/L) inhibited spontaneous or IL-1β-induced NO and PGE_2 production. Both NO and PGE_2 have been reported to be involved in various chondrocytes functions such as apoptosis, MMP activation, growth, and inflammation.[94] Furthermore, neutralization of intra-articular osteopontin with anti-osteopontin serum augmented NO production.[15] These functional studies suggest that one of the roles of intra-articular osteopontin, which is overexpressed in OA cartilage, is to act as an innate inhibitor of IL-1, NO, and PGE_2 production.

Although addition of ECM proteins to cartilage organ cultures causes significant modulation of inflammatory mediators and changes in cartilage homeostasis, one of the main drawbacks of this assay system is that it is not possible to identify the specificity of the matrix ligands, as these ligands have the ability to bind to various receptors on the same cell type.[100,101] For instance, osteopontin can bind to integrins such as $\alpha_v(\beta_1, \beta_3, \text{or } \beta_5)$ dimers and $(\alpha_4, \alpha_5, \alpha_8, \text{or } \alpha_9)\beta_1$ dimers, and also CD44,[102] whereas one of these receptors, $\alpha_v\beta_3$, preferentially binds to osteopontin and to other ligands, such as vitronectin. Thus, it becomes prudent to identify and develop antibodies that competitively inhibit ligand binding (antagonists) and at the same time mimic the function of the ligand (functional agonists) in human cartilage. The $\alpha_5\beta_1$ integrin receptor for fibronectin has been identified on the chondrocytes.[89] Similarly, the $\alpha_v\beta_3$ integrin receptor was also identified on these cell types.[89,103]

The binding of monoclonal antibody JBS5 (which acts as an agonist similar to the N-terminal fragment of fibronectin) to integrin $\alpha_5\beta_1$ up-regulates inflammatory mediators such as NO and PGE_2 as well as the cytokines, IL-6 and IL-8. The $\alpha_v\beta_3$ complex-specific function-blocking monoclonal antibody LM609, which acts as an agonist similar to osteopontin,[102] attenuates the production of IL-1β, NO, and PGE_2 (triggered by $\alpha_5\beta_1$, IL-1β, IL-18, or IL-1β + TNFα + LPS) in a dominant fashion in OA-affected cartilage and in bovine chondrocytes. These data demonstrate a cross-talk in signaling mechanisms among integrins mediated via cartilage matrix components, which also influences 'outside in' and 'inside out' signaling. The dysfunctional signaling mechanisms may influence cartilage homeostasis and its deregulation may play a role in the pathogenesis of OA.[89] This *ex vivo* assay validates ligands and agonist-antagonist interactions in a three-dimensional cartilage system, which may simulate an *in vivo* effect.

Identifying the Role of Matrix Proteins by Phenotype-Driven Functional Genomic Studies

Hyperplasia of synoviocytes is observed in patients with RA and OA, despite differences in underlying etiologies of the two disorders. The autosomal recessive disorder CACP affects the joints and shows synoviocyte hyperplasia. Using a positional-candidate gene approach, Marcelino et al.[46] identified mutations in the gene for CACP (*PRG4*), encoding a secreted proteoglycan previously identified as both 'megakaryocyte-stimulating factor precursor' and 'superficial zone protein'. The *PRG4* gene product, proteoglycan 4, contains domains that have homology to somatomedin B, heparin-binding proteins, mucins, and hemopexins.[46] Functional genomic analysis in mice using a *PRG4* knock-out shows similar cartilage destruction and synovial hyperplasia as that observed in patients with CACP with no infiltrating inflammatory cells.[46]

Hurvitz et al.[104] used a positional candidate approach to map the *WISP3* gene, associated with progressive pseudo-rheumatoid dysplasia (PPD). PPD can be initially misdiagnosed as juvenile RA, and, like RA, shows loss of normal cell columnar organization in the growth zone in the subchondral region of cartilage.[91] The *WISP3* gene is a member of the connective tissue growth factor family, which are secreted and matrix-bound. At least nine different *WISP3* mutations were identified in PPD-affected individuals. The normal function of *WISP3* is unknown. Animal knock-out studies may assist in understanding the mechanism of action of *WISP3*.

4.3.3 Cytokines

Tumor necrosis factors (TNF) and IL-1 are the major pro-inflammatory cytokine known to play a role in chronic and destructive arthritis. TNFα is a critical cytokine, which stimulates other pro-inflammatory molecules such as IL-1β, IL-8, monocyte chemotactic protein (MCP) and vascular endothelial growth factor (VEGF). These molecules in turn exacerbate the disease by recruitment of various inflammatory cells into joints, inducing angiogenesis and matrix metallo-proteinases associated with joint disruption. In the last decade, several therapeutic approaches using anti-TNF molecules have been analyzed in RA in both mouse models of RA and human RA patients. Feldmann and Maini[105] have shown in animal models that by systemic administration of anti-TNF molecules such as the anti-TNF antibody infliximab or the soluble TNFα receptor fusion protein etanarcept can reverse the above observed clinical symptoms and signs. Both of these biologics have been approved by the FDA for treating patients with RA and these drugs have shown consistent and remarkable efficiency in some individuals.

Analysis of Interleukin-1 (IL-1) Signaling in Arthritis

The IL-1 family is one of the most potent pro-inflammatory multifunctional cytokines and has a central role in joint inflammation and synovial lining/cartilage destruction. IL-1 activity resides in each of the two molecules IL-1α and IL-1β, which act by binding to a common receptor, IL-1RI, and the signaling component IL-1 receptor accessory protein (IL-1RAcP). A third member of the IL-1 family, the IL-1 receptor antagonist (IL-1ra), also binds IL-1RI but fails to bring about the interaction with IL-1RAcP. Thus, by blocking the receptor, IL-1ra prevents the action of the agonist IL-1. Additional regulation is provided by IL-1 type II (IL-1RII) or decoy receptor, which binds and sequesters IL-1β, thereby preventing signaling.

Binding of IL-1α or IL-1β to IL-1RI forms a heterodimer with IL-1AcP and evokes signal transduction. This leads to activation of the nuclear factor κB (NFκB) pathway. In contrast, IL-1RII, which also binds to IL-1Acp, functions as an antagonist by capturing excess of IL-1 and blocking IL-1 function. Soluble forms of both the receptor types can be found in plasma and can function as molecular sinks for excess circulating IL-1 protein.

Anakinra, a recombinant human form of IL-1ra, saturates IL-1RI and blocks IL-1 signaling. Anakinra has been studied extensively as monotherapy in arthritis.[106] In view of the importance of IL-1 in arthritis,[103] several homologs of IL-1 and its receptors have been identified from the databank using electronic data mining. These include ST2, an IL-1 receptor homolog, and IL-1H1-H4[107-109] as described in figure 6.

Gene array analysis of human normal and arthritis-affected cartilage showed mRNA expression of *IL1RAP* and *IL1R1* (encoding IL-1RAcP and IL-1R1) are down-regulated in OA cartilage, but not *IL1RN* or *IL1R2* (encoding IL-1Ra and IL-1RII, respectively) are not expressed. Similarly, human synovial and epithelial cells also showed low expression of *IL1R2* mRNA[103] (see figure 6).

IL-1 Polymorphisms in Disease Susceptibility and Severity

Differences in disease severity between individuals with OA and RA could be related to different levels of cytokine production or functional differences resulting from polymorphisms in their genes. Genome-wide linkage scans have highlighted up to 7 chromosomal regions that may harbor OA susceptibility genes, of which chromosome 2q is more promising.[112] In a Finnish study of affected sibling pairs, a region of linkage stretching from 2q12 to 2q21 (where the IL-1 receptor and ligand gene clusters reside) was reported for OA.[113] SNP and variable number tandem repeat (VNTR) polymorphisms in the genes *IL1A*, *IL1B* (encoding IL-1α and IL-1β, respectively) and *IL1RN* have been associated with chronic inflammatory diseases, autoimmune diseases, and gastric cancer.[114,115] Recently, Loughlin et al.[116] genotyped 7 SNPs and 1 VNTR from within the genes of the IL-1 cluster and showed a marginal association of these with OA. Independently, Moos et al.[117] also reported an association between the IL-1 ligand gene cluster and OA. Amin, Thakker and colleagues[118] have reported promoter analysis and IL-1β expression in human chondrocytes,

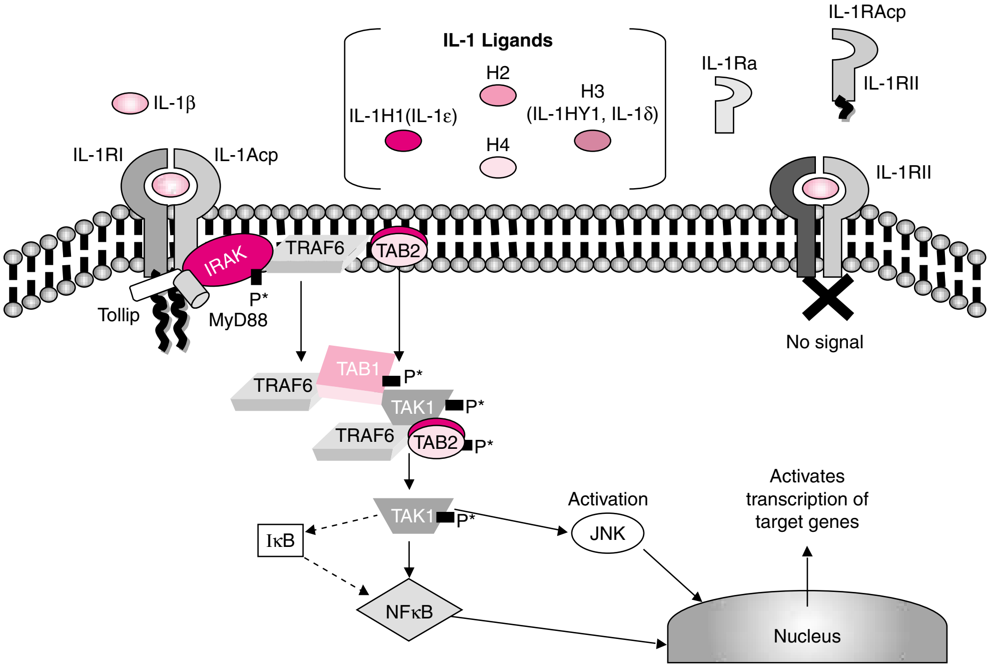

Fig. 6. Interleukin (IL)-1 receptors and signaling mechanisms. IL-1 signaling is regulated by the receptors IL-1 receptor type I (IL-1RI) and IL-1RII. The effects of IL-1 receptors are mediated by IL-1α and IL-1β. IL-1 receptor antagonist (IL-1Ra, anakinra) blocks signaling through the receptor. Accessory proteins (Acp) and receptors interact with IL-1RI during the initial phase of IL-1R-ligand interaction and signal transduction.[110] IL-1RII can also inhibit IL-1 signaling in a similar fashion. Binding of ligands to IL-1RI leads to formation of a complex comprising IL-1RI, IL-1 receptor accessory protein (IL-1AcP), Toll interacting protein (Tollip) and myeloid differentiation factor 88 (MyD88). This complex recruits IL-1 receptor associated kinases (IRAKs) to the inner membrane where it gets phosphorylated, and forms a complex with tumor necrosis factor receptor (TNFR)-associated factor 6 (TRAF6). TRAF6 then translocates from the membrane to cytosol. Membrane bound IRAK also facilitates translocation of IL-1-induced transforming growth factor β (TNFβ) activated kinase 1 binding protein 2 (TAB2) from membrane to cytosol. Translocation of TAB2 and TRAF6 leads to formation of a TRAF6-TAK1-TAB1-TAB2 complex in the cytosol resulting in the activation of TGFβ-activated kinase 1 (TAK1) and, eventually, in IL-1-induced NFκB activation. IL-1β has also been reported to induce p38 MAP kinase, c-Jun-N terminal kinase and p42/p44 ERK MAP kinase in chondrocytes.[111] In contrast, cell-surface IL-1RII (when engaged with IL-1α or IL-1β) binds to soluble IL-1RAcp (IL-1sAcp) and sequesters it, competitively inhibiting the accessory protein from binding to *signaling* IL-1RI. This decoy receptor complex (unlike IL-1RI) does not mediate a signal. The soluble form of IL-1 type II decoy receptor (IL-1RII) is active and binds to IL-1. **IL-1H1-H4** = IL-1 homologos 1-4; **IκB** = inhibitor of NFκB; **TAB1** and **TAB2** = transforming growth factor B activating kinase binding protein.

suggesting the central role of the upstream IL-1 enhancer in regulation of IL-1 genes by IL-1.

In summary, there are significant independent genomic-based reports that suggest that IL-1β may be one of the important players contributing to the effects observed in the joints.

Gene Transfer Approach for Functional Genomics *in Vitro*

The above observations suggest that low concentrations of IL-1β (picogram amounts of IL-1 in gram amount of cartilage), released in human OA-affected cartilage during early stages of the disease,[103] has the ability to act unopposed with respect to the lack of naturally occurring IL-1 antagonistic activity in the cartilage. Thus, low concentrations of functional IL-1 can have detrimental effects on cartilage homeostasis in long-term diseases such as OA. In view of our previous observations,[103] the function of the membrane and soluble form of IL-1RII in human chondrocyte and cartilage homeostasis was examined by reconstituting the receptor in IL-1RII-deficient chondrocytes, synovial cells and epithelial fibroblasts across various species.[103]

Functional genomic analysis showed that recombinant soluble IL-1RII (sIL-1RII), at picomolar concentrations, but not soluble TNF receptor-IgG Fc fusion protein, significantly inhibited IL-1β-induced NO and/or PGE$_2$ production in chondrocytes, synovial and epithelial cells. In OA-affected cartilage, the dose which produces 50% inhibition (IC$_{50}$) of NO production by sIL-1RII was one log order lower than that for sIL-1RI.[103]

Reconstitution of human IL-1RII expression in various IL-1RII-deficient cell types was examined to determine its regulation, specificity and antagonist role using gene transfer approaches. Adenovirus expressing human IL-1RII (AdRSVIL-1RII), when transduced into human and bovine chondrocytes, synovial cells and epithelial cells expressed membrane IL-1RII (mIL-1RII) and spontaneously released functional soluble IL-1RII (sIL-1RII) in the culture supernatants. The IL-1RII$^+$ (but not IL-1RII$^-$) cells were resistant to autocrine and exogenous IL-1-induced effects of

© 2004 Adis Data Information BV. All rights reserved.

NO, PGE_2, IL-6, and IL-8, or decrease in proteoglycan synthesis. Human IL-1RII was functional in various cell types and across species. IL-1RII is cell specific in chondrocytes but also regulates TNFα induced inflammatory mediators in human synovial and epithelial cells. $IL\text{-}1RII^+$ chondrocytes were more resistant to induction of NO and PGE_2 by IL-1 as compared with $IL\text{-}1RII^-$ cells incubated with 100-fold excess of sIL-1RII protein. In cocultures, $IL\text{-}1RII^+$ synovial cells released a functional sIL-1RII, which in a paracrine fashion protected chondrocytes from the effects of IL-1. Furthermore, autologous $IL\text{-}1RII^+$ (but not $IL\text{-}1RII^-$) chondrocytes, when transplanted onto human OA-cartilage *in vitro* showed spontaneous release of sIL-1RII for 20 days, and inhibited the spontaneous production of NO and PGE_2 in cartilage in *ex vivo* conditions.

In summary, reconstitution of IL-1RII in $IL\text{-}1RII^-$ cells using viral and/or plasmid expression vectors significantly protects $IL\text{-}1RII^-$ cells against the autocrine/paracrine effects of IL-1β by acting at several levels of IL-1 signaling and transcription.[103]

Other Cytokines: An Adenoviral-Based Approach to Functional Genomics *in Vivo*

Polymorphism in the *IL1B* gene is associated with inflammation in arthritis,[119] TGFβ1 gene (*TGFB1*) is associated with spinal OA (osteophytosis) and the insulin-like growth factor (IGF) gene (*IGF1*) is associated with generalized OA.[119] Differential expression of mRNA in normal and arthritis-affected cartilage also showed upregulation of *IL1*β, *TGFB1*, and *IGF1* mRNA transcripts.[119,120] The role of IL-1, TGFβ, and IGF in joints can be assessed using a gene therapy approach in a collagen-induced mouse arthritis model and rabbit models to dissect the functions of these growth factors in joint destruction and cartilage homeostasis.

Constitutive intra-articular expression of an adenoviral *IL1B* transgene in rabbit joints induces multiple intra-articular manifestations, which include intense inflammation, leukocytosis, synovial hypertrophy, hyperplasia, highly aggressive pannus formation, erosion of cartilage and bone. It also induced systemic effects including diarrhea and fever. Following the loss of the transgene, (which occurs after 28 days) most of the pathophysiological symptoms described above recur within 4 weeks.[121]

Over-expression of TGFβ by adenovirus in rodent joints induced the formation of osteophytes [122] and deregulation of bone remodeling,[123] in spite of some of its beneficial effects on chondrocyte metabolism.[123] Gene transfer of *IGF1* into rabbit knee joints promotes proteoglycan synthesis without significantly affecting inflammation or cartilage breakdown. No adverse effect of IGF expression was observed on synovium or adjacent muscles. This local gene transfer of *IGF1* to joints could serve as a therapeutic strategy to stimulate new matrix synthesis in both RA and OA.[124] Other target genes (*TSG*-6, *IL4*, *SOD*, *IL1RN*, *IL1RII*, and $p16^{INK4a}$) have also been tested in this model system with success.[125-128]

In summary, a gene therapy approach (*in vitro* or *in vivo*) allows identification of the function of candidate genes in the complex cartilage environment.

5. Conclusions and Future Directions

A simple association of gene expression with disease (e.g. generated through a gene array) does not validate a role for that target gene in the disease. Nor does a human genetic approach to identify targets associated with the disease necessarily generate chemically-tractable molecular targets. Rather the goal of target validation and functional genomics is to strengthen correlative data (from gene arrays, EST libraries, and proteomics) by demonstrating a definitive role for the candidate gene in a disease model. Bioinformatics is an important tool in functional genomics that will help bridge the gap between correlative data and causative data, although there are limitations in predicting *ab initio* gene structure, gene function and protein folds from the raw sequence data. Clearly, much needs to be done, as more than 40% of the 35 000 genes (and possibly 120 000 different proteins they may code) have not been ascribed any functional attribute,[129] either a biochemical function (e.g. kinase), cellular function (e.g. a specific signaling pathway), or function at the organism level (e.g. brain development, immune response, etc.).

As of 1996, successful drug treatments involved fewer than 500 targets or growth factors.[130] It is assumed that at least 5000 of the possible 120 000 proteins may be potential therapeutic proteins or targets, suggesting that only 10% of potential therapeutic strategies have been identified and exploited to date.[131] The gene(s) involved in the etiology of arthritis, subcategorized based on their clinical symptoms, still remain to be identified and characterized among these targets. Genome-based translational research efforts coupled with bioinformatics will facilitate correlating gene expression data with clinical outcomes as described in normal and RA-affected monocytes.[132] These preliminary studies may lead to predictive medicine in arthritis, identifying different disease states, and biomarkers (e.g. therapy-induced remission), with respect to modulation of novel genes.

Arthritis is currently managed with a variety of drugs. On the whole, these drugs treat inflammation and pain as symptoms, but do not address the actual cause of the disease. Some of the new generation of therapeutics in development include vascular adhesion protein 1 (VAP-1) and vascular endothelial growth factor (VEGF) and its receptor FIt-1, which aim to treat the symptoms of the disease. Gene therapy approaches in human RA have given some promising results in phase II clinical trials.[133] Increasing the understanding of molecular cascades involved in the disease processes by genomic approaches will allow us to produce significantly better drugs and biomarkers for predictive medicine than in the future with increased selectivity and fewer adverse effects.

Abstract

Functional gastrointestinal disorders are complex symptom-based disorders without agreed upon biomarkers or pathophysiology. A better understanding of the genetic architecture of these disorders would help to better identify their complex biology and explain the common comorbidity with other disorders of persistent pain, mood, and affect, as well as possibly make it possible to identify subgroups of patients who respond to customized therapies. In contrast to monogenic diseases, polygenic diseases and traits are characterized by the contribution of common variants in a large number of genes, as well as environmental factors, to the vulnerability of an individual. Family and twin studies have clearly established a genetic component in irritable bowel syndrome. Although candidate gene studies have identified a few gene polymorphisms that may be correlated with the syndrome, small sample size, lack of reproducibility in large data sets, and the unreliability of the clinical phenotype require caution when extrapolating to a major role of any of the reported polymorphisms in the pathophysiology of irritable bowel syndrome. Future progress in this area will require better characterization of intermediate phenotypes with large effect size for the clinical phenotype, as well as consideration of gene-gene, environment-gene (epigenetics), and sex-gene interactions, genome-wide association, and whole genome sequencing approaches in large data sets.

Irritable Bowel Syndrome; Intermediate Phenotypes; Candidate Genes; Genome-wide Association Studies

---

Functional gastrointestinal disorders (FGIDs) are part of a spectrum of complex syndromes that are characterized by persistent pain and discomfort referred to different visceral (irritable bowel syndrome [IBS], functional dyspepsia, interstitial cystitis/painful bladder syndrome) and somatic structures (including fibromyalgia and temporomandibular joint disorder).[1] In the absence of reliable biological markers, or a full understanding of the pathophysiology of any of these syndromes, they are currently defined by symptom criteria and sometimes by the exclusion of “organic” disease.[2] In addition to overlap with each other, these syndromes share several clinical and epidemiologic features, including high

comorbidity with symptoms of anxiety and depression, somatization, and stress sensitivity. These similarities have led to the concept that these syndromes, including IBS, share certain pathophysiologic features (eg, central pain amplification) as well as common genetic and environmental vulnerability factors, in addition to having syndrome-specific environmental and genetic factors that are responsible for the individual syndrome manifestation.[1] In the case of FGIDs, such syndrome-specific factors may be related to gastrointestinal function.

There are several fundamental problems when trying to dissect the genetic basis of complex symptom-based disorders, in particular in the case of "functional" disorders that do not have any agreed upon biological marker. The biological mechanisms presenting as symptom-based phenotypes are likely to be heterogeneous. For example, it is likely that certain individuals with mucosal immune activation (eg, lymphocytic colitis; increased mast cell numbers) and those without such changes both meet IBS symptom criteria.[3] In contrast to monogenic diseases, such as cystic fibrosis or Mediterranean fever, in which the variance of the phenotype is completely explained by a single gene, polygenic disorders are determined by many common (and possibly rare) gene variants, each contributing less than 5% and oftentimes much less than 1% of the variance of the clinical phenotype. The common disease/common variant hypothesis states that complex traits result from underlying genetic variants that occur with a relatively high frequency, but the effect size of each of the variants is relatively small.[4,5] A clinical phenotype only emerges if a critical threshold of multiple genetic and environmental factors is reached. The clinical phenotype is not stable. For example, affected patients commonly meet symptom criteria for several of these syndromes at a given time, or at different stages of their lives, and the clinical phenotypes in an individual are not stable over time.[6] Similarly, family histories suggest that relatives and different generations of patients with FGID often do not experience gastrointestinal symptoms but meet criteria of one of the other syndromes. In this review, we will present the current status of our knowledge of the genetic basis of IBS (the FGIDs in which most studies have been conducted), make a critical assessment of these findings, and discuss novel approaches and future directions.

Family and Twin Studies

Familial aggregation has been reproducibly shown in several clinic-based studies of patients with IBS (Table 1), while family studies of other FGIDs are lacking. However, clustering of IBS in families does not necessarily implicate a genetic basis, but could also result from environmental exposures shared in a household, including diet or lifestyle behaviors, exposure to adverse life events within the family, learned cognitions about disease and illness behavior, or even shared exposure to microorganisms.[7,8]

Twin studies are the traditional method used to estimate the genetic and environmental contributions to disease. To date, 5 twin studies of FGIDs, mostly of IBS, have been published (Table 2). Based on these studies, the genetic liability of IBS and FGIDs ranges between 0 and 20% based on concordance rates, and the genetic heritability of FGIDs was estimated to be between 22% and 57%. The variation in heritability estimates likely is due to differences in study methodology. Importantly, in these studies, general shared environment was not a significant predictor of phenotypic variance. However, in the Virginia Twin Study, it was also observed that having a mother or father with IBS was an independent predictor of IBS status, which was stronger than having a twin with IBS, suggesting that social learning or stability of the family environment (which might be influenced by anxiety or depression in one of the parents, disorders often associated with IBS) may have greater influence on the development of IBS than genetics alone.[9]

Candidate Gene Studies

Candidate gene studies are studies whereby investigators postulate that a specific gene, and typically a specific functional gene polymorphism that results in alterations in protein function or quantity, may play a role in disease pathophysiology. The most commonly used approach in IBS to date has been to search for correlations of a candidate gene polymorphism with the symptom-based phenotype IBS (Table 3). More recently, a few studies have aimed to identify correlations between gene polymorphism and biological intermediate phenotypes (see the following text), such as colonic transit, enhanced perception of visceral stimuli, or altered brain responses.[10,11]

Associations of Gene Polymorphisms With Clinical Phenotype

As shown in Table 3, more than a dozen candidate genes have been studied for possible associations with the clinical phenotype of IBS. The majority of genes studied encode serotonin-related proteins (eg, serotonin trans-porter, 5-HT$_3$ receptor, 5-HT$_2$ receptor), proteins involved in noradrenergic signaling (eg, α-adrenergic receptor), and genes encoding immune markers (eg, interleukin-10, transforming growth factor β1). Others genes include the β3 subunit of the G protein (*GNβ3*), cholecystokinin type 1 receptor (*CCK1-R*), Nav1.5 sodium channel (*SCN5A*), and other intestinal epithelial barrier factors.

The best-studied polymorphisms are those related to serotonin (5-hydroxytryptamine [5-HT]) signaling in the brain-gut axis, including the serotonin transporter (SERT), and several 5-HT receptors. This emphasis on genetic variations within the 5-HT signaling system is based on the excellent construct validity of this system from both preclinical[12] and clinical[13] studies. Parallel alterations in central and gut-related 5-HT signaling could explain the typical constellation of altered motility and secretion associated with increased stress responsiveness and increased anxiety. The 5-HTT LPR polymorphism (for serotonin transporter–linked polymorphic region) in the promoter region of the serotonin transporter gene *SLC6A4* is the most intensively studied polymorphism in IBS and has also been studied in psychiatric syndromes,[14] fibromyalgia, and temporomandibular joint disorder.[15–17] Surprisingly, several small case-control studies performed in patients with IBS have shown variable results, and a recent meta-analysis suggests that there is no simple association between this genetic variant and the clinical phenotype of IBS.[18] There has been one study showing a potential association between another functional single nucleotide polymorphism (SNP) (rs25531) on the *SLC6A4* gene with IBS and another study linking the 76G>A SNP on the 5-HT$_3$ receptor type E subunit gene (replicated in a second study) and the 489C>A SNP on the *HTR3C* gene with diarrhea-predominant IBS (IBS-D).

The majority of the other polymorphisms shown in Table 3 have not been found to be associated with the IBS clinical phenotype. However, the majority of these candidate gene/clinical phenotype association studies were small (<200 subjects), did not take into account the caveats addressed in the following section, and with the exception of the 5-HTT LPR and the 5-HT$_{3E}$ gene polymorphism studies have never been replicated in a separate cohort. Due to these limitations, very few of these reported findings allow us to make any conclusions about their validity and, in the opinion of the authors, should not be implicated in the pathophysiology of IBS at this point.

Association of Candidate Gene With Intermediate Phenotype

Intermediate phenotypes, also known as endophenotypes, are biologically related to the clinical phenotype of interest, stable over time and reproducible in different laboratories, detectable at baseline or in the presence of a provocative stimulus, and often present in unaffected family members.[19,20] In contrast to the clinical phenotype, which is based on

NIH-PA Author Manuscript

NIH-PA Author Manuscript

NIH-PA Author Manuscript

subjective and unstable patient reports (see the previous text), intermediate phenotypes are biological or physiologic variables that can be objectively measured and are believed to be more closely related to genetic factors (see Figure 1). This candidate genotype/intermediate phenotype approach has been successfully applied to many polygenic disorders, including chronic pain and schizophrenia.[21] For example, polymorphisms of the *COMT* gene have been associated with objective measures of pain sensitivity[17] and with endogenous opioid release in the brain.[22] Unfortunately, no intermediate endophenotype has been described to date for FGIDs that meets all the criteria previously listed.

Camilleri et al pioneered the intermediate endophenotype approaches in gastrointestinal disorders.[10,11] For example, in one study, several significant gene-sensory and gene-motor associations were observed in IBS and healthy subjects involving several adrenergic and serotonergic gene polymorphisms.[23] Fukudo et al studied the relationship between 5-HTT LPR genotype and regional cerebral blood flow using positron emission tomography during and without colorectal balloon inflation, with the idea that altered brain activation by rectal stimulation might serve as an IBS endophenotype. The 5-HTT LPR polymorphism s/s genotype appeared to be associated with altered brain activation[24,25] and with connectivity within an emotional arousal network with disinhibition of the amygdala,[26] suggesting that this area of the brain may mediate central pain amplification seen in patients with IBS.

Limitations and Interpretation of Current Candidate Gene Studies

False-positive findings—The great majority of findings from small samples (such as those used in most FGID studies) represent false positives that cannot be replicated in a second sample. Because of the large number of genes (20,000) and the even larger number of testable genetic variants (millions), investigators will observe positive associations between hypothesized polymorphisms and complex FGID by chance. Many advocate the use of a higher statistical threshold for significance if multiple genetic variants are tested and/or comparisons (eg, cases vs controls, case-subtype A vs controls, case-subtype B vs controls, and so on) are performed. For example, if 100 SNPs are tested, then the P value to be considered statistically significant after a Bonferroni correction would be .0005. Such high thresholds require either a large genetic effect whereby the variant is very common in cases but relatively uncommon in controls (highly unlikely for FGIDs) and/or very large sample sizes (thousands of patients). Less conservative corrections for multiple comparisons such as the Benjamini–Hochberg approach to controlling the false discovery rate[26] are also available and appropriate but do not entirely alleviate the multiple-testing burden. In addition to sample size, replication of positive studies (lacking for most FGID studies) is critically important, if not an absolute requirement to rule out type I and II errors. Although candidate gene association studies are attractive to test specific hypotheses related to the pathophysiology of FGIDs, the results of one well-designed study still require additional field-based and laboratory-based corroboration before firmly concluding that a genetic variant truly lies in the causal pathway of disease or disorder development.

Disease phenotype—Most studies to date have used conventional symptom-based criteria for defining the presence and type of FGID. The problem with such an approach is that it is dichotomous (eg, affected or unaffected), with no accommodation for intermediate states that are common in polygenic disorders. Similar to many syndromes in psychiatry, such as depression and attention-deficit disorders, such categorical disease definitions are probably artificial because they do not take into account (1) the continuum of symptoms from healthy individuals to health care–seeking patients; (2) the spectrum and overlap of FGIDs with each other as well as other disorders (eg, depression, anxiety, somatization, fibromyalgia); (3) the lack of stability of symptoms over time if disease definition is based on symptom reporting for a set period (eg, "last year," "past 3 months"); and (4) the

NIH-PA Author Manuscript NIH-PA Author Manuscript NIH-PA Author Manuscript

underlying biological mechanisms, grouping people with similar symptoms but different mechanisms for symptom experience or reporting.

Small sample size—Most studies (including all the studies listed in Table 3) do not have sufficiently large sample sizes to address whether a genetic variant may be associated with a specific disorder subtype. It is biologically plausible that a genetic variant may not be causally relevant for the overall disorder but may be responsible for a specific disorder subtype or symptom, particularly if there is clinical and presumed underlying biological heterogeneity. For example, the 5-HTT LPR s allele is not associated with IBS as a group but may be associated with IBS-D or with patients with IBS with high comorbid anxiety. Furthermore, the magnitude of effect of genetic contributors for IBS and other FGIDs is likely quite modest. If at best a few genes contribute about 5% of the variance and the majority less than 1%, and the clinical phenotypes are unreliable (see the introduction), a very large number of subjects (several thousand) are required. In addition, identification of susceptibility loci for FGIDs will likely require a genome-wide approach, testing thousands if not millions of SNPs, whereby multiple-testing issues apply. Finally, analyses studying multiple interactions (eg, gene 1 × gene 2 × environment × sex) will also need to be enlarged to take into account additional variables.

Control groups—Some genetic studies use “convenience” samples of DNA collected from other studies without information about disease/disorder status. Contamination by misclassification may be particularly important for common symptom-based disorders such as FGIDs. Ideally, control subjects should not have a present or past history of an FGID or other comorbid somatic or psychiatric disorders, or a family history of such disorders, and should be recruited prospectively in a similar manner to case recruitment. Also, because functional symptoms present in adulthood and are female predominant, and because genetic variation may differ by race, cases and controls should ideally be matched by age, sex, and race. For example, confounding due to population stratification arises when differences in both allele and disease frequencies exist in a population of mixed racial/ethnic subpopulations. The presence of population stratification could potentially severely bias genetic effect estimates, leading to both false-negative and false-positive results. Most commonly used approaches for adjusting for population stratification include principal components analysis[27] and multidimensional scaling.[28]

Lack of gene-gene, gene-environment, and gene-sex interactions—FGIDs are complex polygenic disorders with significant sex and environmental effects. Prior epidemiologic studies and the previously cited twin studies[9] support this concept, and an extensive literature supports the importance of epigenetic factors in determining the clinical phenotype. For example, it has been shown that unless the environmental factor of adverse life events is taken into account, there is no relationship between the 5-HTT LPR polymorphism and the clinical trait of depression.[29] The effect of adverse early life events influences the adult phenotype through gene modification, such as methylation,[30] and the phenotype of SERT knockout mice varies with the sex of the animal.[31]

Future Directions

Genome-wide Association Studies and Whole Genome Sequencing

More than 100 genome-wide association studies have been conducted for a large number of human diseases, identifying hundreds of polymorphisms with influence on disease vulnerability.[32] However, in most of these studies, one or two genes that had already been known were confirmed, while a large number of common gene variants found in these studies are responsible only for a small fraction of the genetic variation that we know from

NIH-PA Author Manuscript

NIH-PA Author Manuscript

NIH-PA Author Manuscript

family and twin studies. It is likely that a large number of these genes are connected by pathways forming extensive networks with each other and with the various phenotypes. In FGIDs, this approach is further complicated by the fact that in contrast to many of the disease studies with genome-wide association studies (including inflammatory bowel disease), there are few biological markers (such as gastrointestinal transit, gene expression profiles) or validated intermediate phenotypes for FGIDs. Nevertheless, with the anticipated continuing decrease in the costs of performing such genome-wide studies (genome-wide association studies and whole genome sequencing), combined with a consortium approach to study a large number of well-phenotyped patients (as is under way in other complex diseases such as Alzheimer's disease or major psychiatric diseases), such approaches are likely to be applied to FGIDs and related persistent pain disorders in the near future. Systems biological approaches will be required to characterize the complex interactions between hundreds of genes and multiple intermediate phenotypes.[33]

Better Phenotyping

With the rapid advances in large-scale genotyping approaches, the bottleneck in the better understanding of the genetic underpinnings of complex diseases such as FGIDs is the identification and validation of robust intermediate phenotypes (see the previous text). This will require a shift of emphasis from categorical syndrome definition of individual FGIDs ("agnostic approach") and of individual persistent pain disorders to a view of these syndromes as a "mosaic" made up of a large number of interrelated phenotypes.[34] Such correlations between intermediate phenotypes have been reported in a variety of diseases, including disorders of metabolism[35] and schizo-phrenia,[36] and the approach has been adopted in FGID studies by some investigators (see Association of Candidate Genes With Intermediate Phenotype). Among many highly correlated phenotypes, the one with the highest reliability and effect size for the clinical syndrome should be optimal to use for detecting associations with particular genotypes.[34]

Novel Analytic Approaches

As genotyping technology rapidly advances and improves, novel analytic methods need to be developed and appropriately applied. Single SNP analyses using χ^2 tests, Armitage trend tests, and multivariable logistic regression are often sufficient to gain a first impression of genetic associations; however, haplotype-based[37,38] and gene-based and pathway-based methods[39 – 44] often allow a more comprehensive and integrated view of the network of associations and interactions that may exist. Importantly, focus has recently been shifting to the discovery of rare variants via sequencing, and attention should be given to optimal strategies for analyzing next-generation sequencing data.[45– 47]

It is also suggested that some thought be given to whether a purely frequentist approach for assessing evidence for a genetic association should be adopted or whether a Bayesian approach would be more informative. In the frequentist approach, a *P* value is computed for the null hypothesis of no association. However, a *P* value alone does not fully quantify how confident we should be that the variant is truly associated with the phenotype. Bayesian methodology provides an alternative approach that overcomes the limitations of the *P* value (but with the added cost of additional modeling assumptions). The Bayesian approach provides a measure of evidence (the Bayes factor) that allows for a practical and quantitative way of incorporating biological information in the association estimate, allows the direct comparison of SNPs across studies, and provides a comprehensive approach to combining results over several studies in a meta-analysis and across genes in pathway-based analysis.[48] New and innovative statistical methods are rapidly being developed in the hope of facilitating more robust conclusions and interpretable results in future genetic association

studies. Investigators are advised to stay abreast of these statistical advances and to adopt them into their studies.

Summary and Conclusions

Gene discovery for complex polygenic disorders such as FGIDs remains a priority but represents a vast challenge. The field, in particular the individual candidate gene hunting approach, has been hampered by use of discrete and narrow symptom-based definitions—focusing on one disorder such as IBS—instead of objective biological phenotypes. Future studies seeking to identify causal genetic loci for FGIDs will likely use a combination of approaches, with candidate gene as well as genome-wide approaches. Whole genome sequencing in combination with expression profiling and novel analysis techniques will not only enable researchers to identify variations in individual genes, but also the effect of epigenetic processes such as gene methylation on gene expression, reflecting environmental influences (Figure 2).

Figure 1.

Intermediate phenotype strategy for FGIDs and frequently comorbid disorders. Shown is the progressive deconstruction of clinical, symptom-based syndromes (several examples are shown in the first row) into intermediate phenotypes (examples are shown in each row) all the way down to the genome. For clarity, only a small number of candidate genes are shown. Although the syndrome and the symptoms can only be studied in humans, the neurobiological endophenotypes can be studied both in humans and in animal models. It has been postulated that the correlation between neurobiological endophenotypes and genes is significantly higher than the correlation between clinical syndromes and genes. Simplified model for interaction between genes, peripheral and central endophenotypes, and environmental factors resulting in IBS symptoms. Individual genes influence the function of neural networks in the brain and in the enteric nervous system (including closely related gut cells). Alterations in these neural systems result in alterations in central and peripheral systems related to pain perception, autonomic arousal, peristalsis, and secretion. Significant interactions of genetic with epigenetic factors (including microflora environmental stressors) and with the sex of the individual are likely. ABSTRACT

Host antiviral genes are important regulators of antiviral immunity and plausible genetic determinants of immune response heterogeneity after vaccination. We genotyped and analyzed 307 common candidate tagSNPs from 12 antiviral genes in a cohort of 745 schoolchildren immunized with two doses of measles–mumps–rubella (MMR) vaccine. Associations between SNPs/haplotypes and measles virus-specific immune outcomes were assessed using linear regression methodologies in Caucasians and African-Americans.

Genetic variants within the *DDX58*/RIG-I gene, including a coding polymorphism (rs3205166/Val800Val), were associated as single-SNPs ($p \leq 0.017$; although these SNPs did not remain significant after correction for false discovery rate/FDR) and in haplotype-level analysis, with measles-specific antibody variations in Caucasians (haplotype allele p-value = 0.021; haplotype global p-value = 0.076). Four *DDX58* polymorphisms, in high LD, demonstrated also associations (after correction for FDR) with variations in both measles-specific IFN-γ and IL-2 secretion in Caucasians ($p \leq 0.001$, $q = 0.193$). Two intronic *OAS1* polymorphisms, including the functional *OAS1* SNP rs10774671 ($p = 0.003$), demonstrated evidence of association with a significant allele-dose-related increase in neutralizing antibody levels in African-Americans. Genotype and haplotype-level associations demonstrated the role of *ADAR* genetic variants, including a non-synonymous SNP (rs2229857/Arg384Lys; $p = 0.01$), in regulating measles virus-specific IFN-γ Elispot responses in Caucasians (haplotype global p-value = 0.017). After correction for FDR, 15 single-SNP associations (11 SNPs in Caucasians and 4 SNPs in African-Americans) still remained significant at the q-value < 0.20.

In conclusion, our findings strongly point to genetic variants/genes, involved in antiviral sensing and antiviral control, as critical determinants, differentially modulating the adaptive immune responses to live attenuated measles vaccine in Caucasians and African-Americans.

1. Introduction

The attenuated measles vaccine offered the opportunity to considerably reduce measles-related morbidity and mortality. However, measles is still a public health issue with approximately 164,000 deaths in 2008 worldwide [1] and with a relative increase in reported cases in several European countries and in the United States, including cases in individuals after two doses of MMR vaccine [2–6]. Therefore, establishing effective measles immunity across the population is crucial and requires providing both immunization coverage and surveillance to detect new cases and outbreaks [7]. Despite measles control (but not eradication), questions still remain regarding the documented 2–10% primary failure rate after vaccination, and the immunogenetic causes of vaccine response heterogeneity and/or vaccine failure. Deeper understanding of the observed inter-individual differences in immune response to measles vaccine is needed to provide new insights for improving vaccine-induced humoral, cellular, and innate immune responses, and for designing better vaccines [8,9].

The first line of defense, innate immunity, orchestrates host responses to prevent or reduce viral replication and spread until the adaptive immune system is switched on to eliminate the specific invading pathogen. Cellular viral sensors, type I and III interferons (IFNs, IFNα/β, IFN λ1, IFN λ2, IFN λ3) and IFN-triggered

doi:10.1016/j.vaccine.2011.09.043

antiviral proteins have long been recognized as crucial mediators of innate antiviral defense with important effects on the magnitude and quality of innate and adaptive immune responses. Important antiviral factors and pathways, such as the retinoic acid-inducible gene I protein (*RIG-I*/*DDX58*), melanoma differentiation associated protein-5 (*MDA-5*/*IFIH1*), mitochondrial antiviral signaling protein (*MAVS*/*VISA*/*IPS1*/*CARDIF*), dsRNA-activated protein kinase R (*PKR*/*EIF2AK2*), the 2′–5′-oligoadenylate-synthetase (*OAS*) – ribonuclease L (*RNASEL*) pathway, Mx protein GTPases, adenosine deaminase, RNA-specific 1(*ADAR*), the *ISG15* ubiquitin-like pathway and others play a role in viral sensing, control, pathogenesis and outcome of viral infections [10–13]. Polymorphisms in IFN-stimulated antiviral effector genes and cellular viral sensors are potential genetic determinants of immune response heterogeneity that may influence the immune responses to viral vaccines by altering the functionality and antiviral effects of the corresponding proteins. Genetic variants in these genes have been implicated as important regulators of immunity and host response to infection [14–24].

Bearing in mind the multifaceted interactions between viruses and factors of the innate immune system, our study sought to investigate for the first time the role of key antiviral effector proteins and cellular antiviral sensors as plausible contributors to immune response heterogeneity to live attenuated measles vaccine. For this reason, we performed a comprehensive candidate gene association study in a large racially diverse cohort of healthy schoolchildren after two doses of MMR vaccine. Our results suggest that multiple innate immunity genetic variants/genes are likely involved in modulating the adaptive immune responses to live attenuated measles vaccine in Caucasians and African-Americans.

2. Materials and methods

2.1. Study subjects and demographics

Our study cohort consisted of 2 independent age-stratified samples of randomly recruited healthy schoolchildren and young adults from Olmsted County, Minnesota, as described previously [25,26]. Briefly, cohort 1, enrolled in 2006–2007, comprised a sample of 440 subjects (age 11–19 years), from which 388 were eligible for the current study [14–16]. Cohort 2, enrolled in 2008–2009 year, consisted of 376 eligible subjects (age 11–22 years). All study participants resided in a community where no cases of measles infection had been reported during their lifetimes and all had received two doses of MMR-II vaccine (Merck, Whitehouse Station, N.J.), containing the Edmonston strain of measles virus ($TCID_{50} \geq 1000$). The Mayo Clinic Institutional Review Board granted approval for the study. Written, informed consent was obtained from parents/guardians as well as written assent from age-appropriate subjects at the time of enrollment in the study.

The demographic and clinical variables of the study cohort have been described previously [25,26]. Briefly, the study cohort ($n = 745$ subjects) used in our genetic association study, consisted of 417 males (55.97%), and 328 females (44.03%). The two most prevalent racial groups used were Caucasians (598, 80.27%) and African-Americans (89, 11.95%). Most of the study subjects were non-Hispanics (723, 97.05%). The median age at enrollment was 15 years (inter-quartile range/IQR 13; 17) and the median age at first and second immunization was 15 months (IQR 15; 16) and 5 years (IQR 4; 11), respectively. The median time from second immunization to enrollment and immunity measurements was 7.4 years (IQR 5.6; 9.2).

2.2. Immune measures

2.2.1. Plaque Reduction Microneutralization Assay (PRMN)

We measured neutralizing antibodies to measles virus using a high throughput fluorescence-based PRMN, as previously described [27], with the following modifications in the readout. We used an automated Olympus IX71 Fluorescent microscope system with Image-Pro Plus Software Version 6.3 (MediaCybernetics) to scan and count GFP-positive plaques [25]. Calculations of 50% end point titer (Neutralizing Dose, ND_{50}) were performed using Karber's formula and ND_{50} values were transformed into mIU/mL values using the 3rd WHO international anti-measles antibody standard (NIBSC code no. 97/648) as previously described [27].

2.2.2. Elispot

Human total IFN-γ Elispot kits (R&D Systems, Minneapolis, MN) were used to measure the number of IFNγ-producing cells, as previously described [28] following the manufacturer's protocol. Briefly, we stimulated subjects' peripheral blood mononuclear cells/PBMCs (or alternatively left them unstimulated), in triplicate, with the Edmonston strain of measles virus (multiplicity of infection, MOI = 0.5) and developed the reaction after 42 h incubation at 37 °C, in 5% CO_2. Phytohaemagglutinin/PHA (5 μg/mL) was used as a positive control. All plates were scanned and analyzed using the same counting parameters on an ImmunoSpot® S4 Pro Analyzer (Cellular Technology Ltd., Cleveland, OH, USA) using ImmunoSpot® version 4.0 software (Cellular Technology Ltd.).

2.2.3. ELISA

Secreted cytokines (Th1: IL-2, IFN-γ; Th2: IL-10; and innate/inflammatory: IL-6, TNF-α, IFN-α, IFN-λ1) were quantified in PBMC cultures after in vitro stimulation with live measles virus (stimulated and unstimulated in five replicate measurements), using pre-optimized conditions for MOI and incubation time for each cytokine, as previously described [29,30]. The different cytokines are measured using the following conditions: IFN-α and TNF-α MOI = 1.0, 24 h; IL-2 and IL-10 MOI = 0.5, 48 h; IL-6, IFN-γ and IFN-λ1 MOI = 1.0, 72 h. Secreted cytokine levels were measured with commercial kits according to manufacturers' recommendations (R&D Systems, Minneapolis, MN, for IFN-λ1; Mabtech, Cincinnati, OH, for IFNα, and BD Biosciences Pharmingen, San Diego, CA for the rest of the cytokines).

2.3. SNP selection and genotyping of SNPs in antiviral genes

The SNP selection approach and genotyping methodology have been published for our previous genetic association studies [14–16,26]. Briefly, we used the tagSNP selection approach based on linkage disequilibrium (LD) [31] to select SNPs from each of 12 antiviral genes, including the regions 5 kb upstream and downstream for each gene, from the source with the greatest number of SNPs from among the Hapmap Phase II (http://www.hapmap.org), Seattle SNPs (http://pga.mbt.washington.edu/) and NIEHS SNPs (http://egp.gs.washington.edu/). We binned SNPs with a minor allele frequency (MAF) ≥ 0.05, a pairwise LD threshold of $r^2 \geq 0.90$, and successful Illumina predictive genotyping scores, for the Caucasian sample and African-American sample separately, using the ldSelect program [31]. To accommodate a set of Illumina platform constraints, the SNP list was further post-processed and refined using the SNPPicker program. We also added a set of functional "obligate" SNPs (coding: nonsynonymous, synonymous, 5′ or 3′ untranslated regions) to the final list. A total of 348 SNPs across 12 antiviral genes were selected based on this approach. The nomenclature used for the description of the polymorphisms follows that described by den Dunnen and Antonarakis [32].

We genotyped the selected 348 SNPs using two custom Illumina GoldenGate SNP panels (Illumina Inc., San Diego, CA) for 1536 and 768 SNPs, which were used for genotyping all candidate SNPs from a large population-based measles vaccine study. All DNA samples ($n = 764$) were genotyped following the manufacturer's protocol and as previously described [14].

Seven hundred and sixty four ($n = 764$) subjects were initially genotyped for 348 known SNPs in 12 antiviral genes with a documented role in antiviral immunity (*DDX58/RIG-I*, *MAVS/VISA*, *IFIH1/MDA5*, *MX1*, *MX2*, *OAS1*, *OAS2*, *OAS3*, *PKR/EIF2AK2*, *RNASEL*, *ADAR* and *ISG15*). The genotyping locus success rate was 94.55%, sample success rate was 98.75% (including replicate samples), and reproducibility was 100%. Due to insufficient/inadequte DNA quality, genotyping failure or low call rates, nineteen DNA samples failed, leaving 745 subjects for further analysis. Of the 348 SNPs included for genotyping, eighteen SNPs failed the initial quality control because of failure to amplify, poor clustering or multiple replicate errors. 330 SNPs (95.12%) yielded genotyping data. Additional SNPs were also excluded from analysis based on low MAF < 0.05 ($n = 20$) or based on being monomorphic ($n = 3$). A total of 307 SNPs were used for the final race-specific analysis in 598 Caucasians and 89 African-Americans.

2.4. Statistical methods

The statistical methods described herein are similar to those published for our previous genetic association studies [14–16,26]. Data were descriptively summarized using frequencies and percentages for categorical variables, and medians and inter-quartile ranges for continuous variables. Assessments of cytokine secretion and cell-mediated immunity (CMI) measures resulted in multiple recorded values per outcome both prior to and after stimulation with measles virus. For descriptive purposes, a single response measurement per individual was obtained for each of these outcomes by subtracting the median of the unstimulated values from the median of the stimulated values. Assessments of antibody levels resulted in only one recorded value per individual.

Observed genotypes were used to estimate allele frequencies for each SNP and departures from Hardy-Weinberg equilibrium (HWE) were assessed using either a Pearson goodness-of-fit test or, for SNPs with a minor allele frequency (MAF) of less than 5%, a Fisher exact test [33]. Estimates of pair-wise linkage disequilibrium (LD) based on the r-squared statistic were obtained using Haploview software, version 3.32 [34].

SNP associations with immune response outcomes were evaluated using regression models. Simple linear regression was used for measles antibody levels, for which we had only one measured value per individual. Repeated measures approaches were implemented for the cytokine secretion and IFN-γ Elispot variables, simultaneously modeling the multiple observed measurements and using an unstructured within-person variance–covariance matrix to account for within-subject correlations. This was achieved by including the genotype variable in the regression model, together with a variable representing stimulation status. The resulting genotype-by-stimulation status interaction was then tested for statistical significance. Tests of association assumed an ordinal (log-additive) SNP effect using simple tests for trend. Because of the lack of seronegative subjects (PRMN titer < 1:8) in our cohort and the low number of subjects (68) with antibody concentrations less than the protective threshold of 210 mIU/mL (corresponding to PRMN titer of 120) [25], our statistical approach rationale was to assess associations between SNPs and quantitative humoral/cellular immune outcomes across the entire cohort using linear regression methodologies rather than assess the distribution of SNPs across extremes of humoral/cellular immune responses (such as seronegative subjects and/or subjects with antibody concentrations less than the protective titer).

To further explore genomic regions containing statistically significant single-SNP effects, we performed post hoc haplotype analyses. Posterior probabilities of all possible haplotypes for an individual, conditional on the observed genotypes, were estimated using an expectation–maximization (EM) algorithm [35]. This information was used to define haplotype design variables that estimated the number of each of the haplotypes carried by an individual. Analyses were performed on all resulting common haplotypes (those with an estimated frequency of >1%) using simple least squares linear regression approach for antibody levels and repeated measures approaches for the CMI variables. Differences in immune response among common haplotypes were first assessed globally and simultaneously tested for statistical significance using a multiple degree-of-freedom test. Following these global tests, we examined individual haplotype effects. Each haplotype was included in a separate regression analysis, effectively comparing immune response levels for the haplotype of interest against all others combined. Due to phase ambiguity, haplotype-specific medians and inter-quartile ranges could not be calculated. Thus, descriptive summaries were represented using the corresponding t-statistics.

All of the association analyses described above were separately performed within the two most prevalent racial groups (Caucasians and African-Americans). Each analysis also adjusted for gender, age at first measles vaccination, age at second measles vaccination, age at enrollment (thus accounting for the time since last vaccination to enrollment/blood draw and immunity measurements), and cohort status (cohort 1 vs. cohort 2). We used an inverse normal transformation for all cytokine secretion and IFN-γ Elispot outcome variables, and a log transformation for the antibody response measure, in all formal tests to account for the skewed nature of the data. Because of the large number of statistical tests, we computed q-values for each SNP to estimate the corresponding false discovery rates (FDR) as per Storey and Tibshirani [36,37]. We considered SNPs as being significant if their q-value was less than 0.2 [38]. However, we also reported single-SNP associations as being of interest for further follow-up if the q-value was less than 0.5. This corresponded to single-SNP p-values that were roughly ≤ 0.01. All statistical tests were two-sided and, unless otherwise indicated, all analyses were carried out using the SAS software system (SAS Institute, Inc., Cary, N.C.).

3. Results

3.1. Immune responses for the study cohort

The immune characteristics of the study cohort are summarized in Table 1. The median level of measles-specific neutralizing antibodies (humoral immunity) for the study cohort was 846 mIU/mL (inter-quartile range/IQR: 418, 1772) and the median IFN-γ Elispot response (cellular immunity) was 36 IFN-γ-positive spots per 2×10^5 cells (IQR: 12, 69). The median measles-specific IFN-γ secretion level for the cohort was 67 pg/mL (IQR: 35, 120), the median measles-specific IL-2 secretion level was 38 pg/mL (IQR: 21, 64), and the median measles-specific IL-10 secretion level was 18 pg/mL (IQR: 11, 28) [26].

3.2. Genetic associations

3.2.1. Associations between SNPs in antiviral genes and humoral immune responses after measles vaccination

Race-specific analysis in the Caucasian group identified two significant associations between SNPs located in antiviral genes and neutralizing antibody levels after measles vaccination ($p \leq 0.01$), as well as one suggestive SNP association with $p = 0.017$ (Table 2). An intronic SNP in the *DDX58* (RIG-I) gene (rs11795343) was associated with an allele dose-related increase (19%, calculated as the ratio, minus one, of the immune outcome observed for the homozygous minor allele genotype to the immune outcome observed for the homozygous major allele genotype, multiplied

Table 1
Immune characteristics of the study cohort.

Response type	Cytokine	No. of subjects	Median response (IQR)[a]	No. subjects positive (%)[b]
Neutralizing antibody	–	744	846 (418; 1 772)	686 (92.2)
Th1	IL-2	739	38 (21; 64)	724 (98.0)
	IFNγ	737	67 (35; 120)	716 (97.2)
Th2	IL-10	740	18 (11; 28)	726 (98.1)
Innate/inflammatory	IL-6	737	355 (248; 461)	726 (98.5)
	TNFα	732	14 (9; 19)	722 (98.6)
	IFNα	734	551 (273; 1 025)	729 (99.3)
	IFNλ1	738	34 (14; 73)	666 (90.2)
Elispot	IFNγ	707	36 (12; 69)	676 (95.6)

[a] Humoral response is defined as the measles-specific mIU/mL titer in PRMN assay. Cytokine response is defined as the subject-specific median measles-stimulated response (measured in five replicates) minus the median unstimulated response (also measured in five replicates). Elispot response is defined as the subject-specific median measles-stimulated response (measured in triplicate) minus the median unstimulated response (also measured in triplicate). Values reported are in mIU/mL for antibody responses, pg/mL for secreted cytokines, and cytokine-positive spots per 2×10^5 cells for Elispot responses ± IQR, inter-quartile range.

[b] For antibody responses subjects reported as positive are with positive protective titers higher than the protective threshold of 210 mIU/mL (corresponding to ND_{50} 120). Subjects are considered to have a positive cytokine response if the median of the stimulated cells is larger than the median of the unstimulated cells.

by 100%) in antibody levels ($p = 0.01$). This intronic SNP was found to be in LD ($r^2 = 0.64$) with a synonymous *DDX58* SNP (rs3205166/Val800Val), which also demonstrated an allele dose relationship with higher neutralizing antibody levels (approximately 40% increase in antibodies), although this association did not reach statistical significance at $p \leq 0.01$ ($p = 0.017$, Table 2). In addition, eight more *DDX58* SNPs displayed suggestive associations with antibody levels in this racial group ($p < 0.05$, data not shown). An intronic genetic variant within the *VISA* gene demonstrated an association with antibody levels in the Caucasian group ($p = 0.003$).

The analysis restricted to the African-American subjects revealed three significant intronic SNP associations with measles-specific humoral immune response ($p \leq 0.01$, Table 2). Importantly, this analysis identified an association for a functional genetic variant rs10774671 located in intron 5 of *OAS1*, at the splice-acceptor site [39]. The minor alleles of the two *OAS1* intronic SNPs, rs10774671 and rs10744785, were associated with a significant increase (more than a 3-fold increase for rs10774671 and 4.9-fold increase for rs10744785) in measles neutralizing antibodies in an allele dose-related manner ($p \leq 0.003$, Table 2).

However, after adjusting for false discovery rate (FDR), none of the identified SNPs listed in Table 2 remained significant at the q-value = 0.20 [38], although all reported SNP associations demonstrated q-values < 0.5 and two SNP associations demonstrated q-values < 0.25.

3.2.2. Associations between SNPs in antiviral genes and cellular immune responses (INF-γ Elispot) after measles vaccination

Race-specific analysis in the Caucasian group revealed six significant associations between genetic variants in two antiviral genes (*OAS3* and *ADAR*) and measles-specific IFN-γ Elispot responses ($p \leq 0.01$, Table 3). Four *ADAR* SNPs in high LD ($r^2 \geq 0.96$), including a non-synonymous *ADAR* SNP (rs2229857/Lys384Arg), demonstrated an allele dose-related increase (29% for rs2229857) in IFN-γ Elispot responses in this racial group with the representation of the minor allele ($p \leq 0.01$, Table 3). Furthermore, we observed three additional *ADAR* SNPs, which demonstrated suggestive associations

Bolded SNPs are associated with an allele dose-related increase/decrease in median IFN-γ Elispot responses.

[a] Values are presented as homozygous major allele/heterozygous/homozygous minor allele. *N* indicates the number of subjects with the specific genotype, % indicates genotype counts in percentages.

[b] Results are presented as median IFNγ-positive spots per 2×10^5 cells ± IQR (inter-quartile range), as measured by the total IFNγ Elispot assay.

[c] Ordinal *p*-value from the repeated measures linear regression analysis adjusting for age at enrollment, gender, age at first and second immunization, and cohort status.

[d] Corresponding *q*-values, adjusting for FDR.

with the immune outcome in the Caucasian group ($p < 0.05$, data not shown).

The analysis in the African-American group revealed five associations for SNPs belonging to five antiviral genes with measles-specific cellular immunity ($p \leq 0.009$, Table 3). A synonymous *OAS3* polymorphism (rs2072136/Ser567Ser) was found to be associated with IFN-γ Elispot responses in this racial group ($p = 0.007$, Table 3). The minor alleles of two intronic SNPs, *EIF2AK2* SNP rs12712526 ($p = 0.001$) and *MX2* SNP rs466092 ($p = 0.006$), demonstrated significant allele dose-related variations (decrease and increase, respectively) in the immune outcome (Table 3).

After adjusting for false discovery rate (FDR), none of the identified SNPs in Table 3 remained significant at the *q*-value = 0.20 [38], although all reported SNP associations demonstrated *q*-values < 0.5 and one SNP association demonstrated *q*-values < 0.25.

3.2.3. Associations between DDX58 and ADAR haplotypes and measles vaccine-induced immunity in Caucasians

To further explore genomic regions enriched with statistically significant ($p \leq 0.01$) and suggestive ($p < 0.05$, data not shown) single-SNP associations, we performed haplotype analyses for the *DDX58* and *ADAR* gene regions.

The haplotype level analysis revealed that genetic variants/haplotypes within the *DDX58* and *ADAR* genes (Haploview output presented in Fig. 1) were associated with measles-specific humoral and cellular immunity (IFN-γ Elispot), respectively, in Caucasians, but not in African-Americans (*DDX58* haplotype allele *p*-value = 0.021; *ADAR* global *p*-value = 0.017, Table 4). Particularly, the *DDX58* haplotype GGAAAAAAAA was associated with decreased antibody levels (haplotype *t*-statistic = −2.31; allele *p*-value = 0.021) compared to all other *DDX58* haplotypes, while the *ADAR* haplotype ATAATCGGGAAAGGAA was associated with increased IFN-γ Elispot response (haplotype *t*-statistic = 2.82; allele *p*-value = 0.005) in the Caucasian group (Table 4).

3.2.4. Associations between SNPs in antiviral genes and secreted cytokines after measles vaccination

We found 58 and 47 significant associations ($p \leq 0.01$) in the Caucasian and African-American group, respectively, between genetic variants in antiviral effector genes and measles-specific secretion of Th1, Th2 and innate/inflammatory cytokines, however most of the SNP associations (with cytokine secretion immune outcomes) did not meet the FDR threshold of 0.20 [38]. Analysis in the Caucasian group revealed seven significant SNP associations with measles-specific IFN-γ secretion, which remained significant at

[b] *ADAR* genetic variants from left to right: rs3811450, rs6656743, rs9427092, rs1127326, rs9616, rs1127317, rs1127311, rs2131902, rs3738032, rs2229857, rs3738029, rs3766922, rs12125166, rs9427100, rs2335230, and rs884618 (all genotyped in the current study).

[c] Haplotype effects (for haplotypes with estimated frequencies ≥0.01) are calculated using the haplotype *t*-statistic, which shows the direction and magnitude of the estimated haplotypic effect on the immune measure.

[d] Allele *p*-values compare individual haplotypes to all other haplotypes combined; global *p*-values reflect differences in immune response among common haplotypes as assessed globally and tested for statistical significance using a multiple degree-of-freedom test. Statistically significant *p*-values for haplotype-level associations ($p < 0.05$) are highlighted in bold. Analyses are adjusted for age at enrollment, gender, age at first and second MMR immunization and cohort status (cohort 1 or cohort 2).

the *q*-value = 0.20 [38] after adjusting for FDR ($p \leq 0.001$, $q = 0.193$; Table 5). Two *MX2* intronic SNPs demonstrated an allele–dose relationship with lower IFN-γ secretion levels ($p \leq 0.001$). In addition, the minor alleles of four *DDX58* SNPs (in high LD; for rs12555727, 12006123 and rs17289116, $r^2 = 1$) were associated with a significant allele dose-related decrease (approximately 30%) in secreted IFN-γ in the Caucasian group (Table 5). Interestingly, the same four *DDX58* SNPs demonstrated a more than 2-fold reduction in measles-specific IL-2 secretion levels (with the representation of the minor allele) in the Caucasian group and still remained significant after adjusting for FDR ($p \leq 0.001$, $q = 0.193$, Table 6). Of note, three of the *DDX58* SNPs (rs12555727, 12006123 and rs17289116, $r^2 = 1$) were also found to be associated at the haplotype level with variations in measles-specific humoral immunity in Caucasians (Table 4).

The analysis in the African-American group revealed four significant SNP associations with measles-specific IL-10 secretion, which remained significant at the *q*-value = 0.20 [38] after adjusting for FDR ($p \leq 0.0003$, $q \leq 0.192$; Supplementary Table 1). In particular, the minor alleles of two SNPs in the 3′ intergenic region of the *MX1*

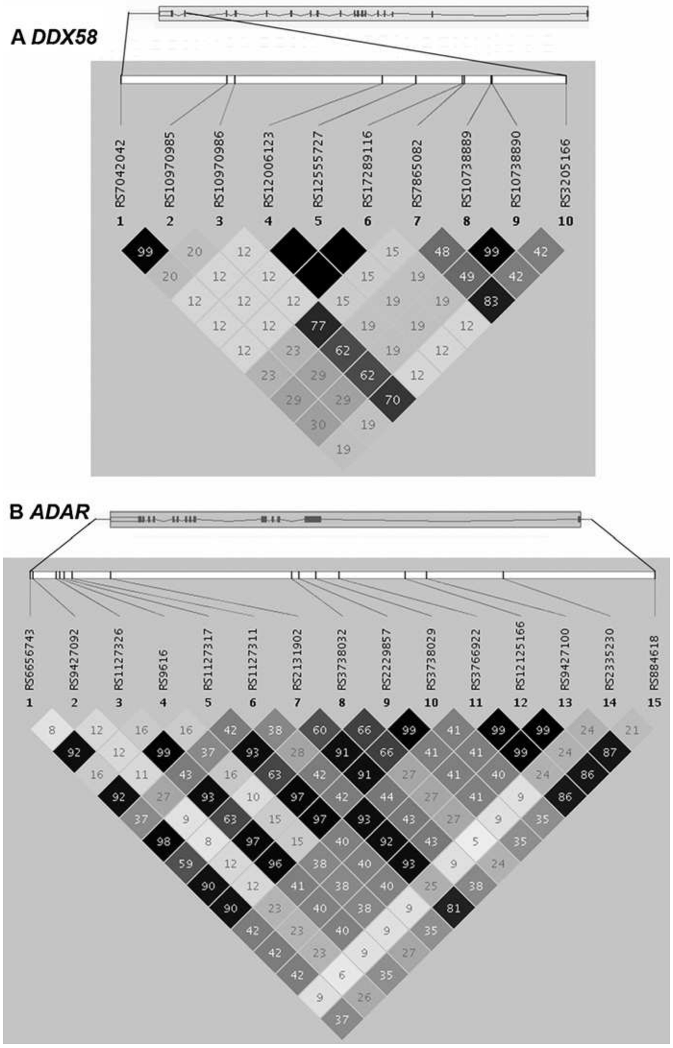

Fig. 1. Haplotype block structure of the *DDX58* and *ADAR* genetic variants in the study cohort (Caucasian sample). The schematic gene representation and LD block structure of (A) *DDX58* and (B) *ADAR* genetic variants is depicted. The LD block structure was analyzed using Haploview software, version 3.32. All SNPs presented in A and B were directly genotyped in the study. The r^2 color scheme is: white ($r^2 = 0$), shades of grey ($0 < r^2 < 1$), black ($r^2 = 1$). The numbers report the r^2 value multiplied by 100.

gene (in high LD) were associated with a significant increase in IL-10 secretion in an allele dose-related manner ($p = 0.0002$, $q = 0131$; Supplementary Table 1).

To summarize, we identified two *DDX58* and four *ADAR* genetic variants, as well as *DDX58* and *ADAR* haplotypes, associated with neutralizing antibody levels and measles-specific cellular immunity (IFN-γ Elispot), respectively, in our Caucasian group. Four *DDX58* polymorphisms (associated with neutralizing antibody variations at the haplotype level) demonstrated significant associations with variations in both IFN-γ and IL-2 secretion in Caucasians. Two *OAS1* genetic variants, including the functional *OAS1* SNP rs10774671, were associated with humoral immune response variations in our African-American group.

4. Discussion

Various genetic variants and genes have been implicated as important regulators of immunity to viral vaccines (including measles vaccine), such as cytokine and cytokine receptors, toll-like receptors (TLRs) and signaling molecules, viral receptors (such as CD46, SLAM and DC-SIGN for measles virus) and vitamin A and D receptors [15,16,26,38,40–47]. The objective of our population-based study was to comprehensively evaluate the influence of human genetic variation in key host antiviral sensor and antiviral effector genes on immune response heterogeneity after measles vaccination.

Genetic polymorphisms (SNPs) in genes related to innate immunity, such as the interferon β gene (*IFNB1*), type I IFN receptor genes *IFNAR1* and *IFNAR2*, the antiretroviral gene *TRIM5* and *TLRs* are known to be associated with variations in immune responses to measles and rubella vaccines [15,16,38,43,48]. We have previously demonstrated that specific variations in antiviral sensor genes (*DDX58*/*RIG-I* and *MAVS*/*VISA*) and key IFN-induced antiviral genes (particularly polymorphisms in the *OAS* gene cluster) were associated with differences in rubella vaccine-induced adaptive immunity [14–16], while little is known regarding the importance of these genes or variations in measles-specific immunity. Furthermore, multiple previous genetic association studies revealed that polymorphisms in the *MX1*, *OAS1*, *OASL* and *PKR* genes correlate with response to IFN therapy and/or susceptibility to viruses such as WNV, HCV, HBV, SARS-coV, and measles virus [17–24].

Our genetic data from single SNP and haplotype analyses point to the possible involvement of genetic variants within the *DDX58* (RIG-I) gene, including a coding polymorphism (rs3205166/Val800Val), in antibody variations following measles vaccine in Caucasians (haplotype allele p-value = 0.021). Mitochondrial antiviral pathways involve the detection of viral RNA by cytosolic helicases belonging to the RIG-I-like helicase family (RIG-I/*DDX58* and MDA5/*IFIH1*), and downstream signaling through interaction with the IPS-1 (*VISA*/*MAVS*/*CARDIF*) adaptor protein [49,50]. In addition, vitamin A and its metabolites, which are known to affect measles replication and antibody responses after vitamin supplementation, are linked with RIG-I/DDX58 through RARα and IFN type I-dependent mechanism [51,52]. Genetic variants within these antiviral sensor genes were associated with different measles-specific immune outcomes in our study (including common *DDX58* genetic variants regulating both antibody responses, and measles-specific IFN-γ and IL-2 secretion in the Caucasian group), which is consistent with a recent report of the recognition of measles virus by RIG-I and MDA5 to instigate interferon-specific innate immune responses [53]. Interestingly, a common coding functional *DDX58* polymorphism (rs10813831/Arg7Cys), known to modulate *IFNB1* and *DDX58* transcription in dendritic cells [54], and suggested as a plausible regulator of rubella vaccine-induced humoral immunity [15], was associated with measles-specific IFN-α secretion in the African-American sample, although did not remain significant after adjusting for FDR ($p = 0.005$, $q = 0.447$, data not shown).

In addition, our analysis of genetic associations with measles-specific vaccine responses revealed enriched representation of genetic variants within the OAS cluster of genes: *OAS1*, *OAS2* and *OAS3* (Tables 2, 3 and 5, Supplementary Table 1). The interferon-induced OAS1 protein is known to catalyze the synthesis of 2′,5′-oligoadenylates, which activate RNase L, resulting in antiviral (viral RNA degradation, inhibition of viral replication) and pro-apoptotic activities, and genetic polymorphisms in the coding genes have been linked to various immunological and infectious outcomes [21–24]. The involvement of *OAS* genetic variants in regulating measles vaccine–immune responses is highly plausible bearing in mind that *OAS* genetic variations are likely involved in modulating the adaptive immune responses to live attenuated rubella vaccine [14]. Particularly convincing is the association of *OAS1* SNP rs10774671, a polymorphism with established functionality, with variations in measles-specific humoral immune responses (more than 3-fold increase associated with the homozygous minor allele genotype) in the African-American sample ($p = 0.003$). This genetic variant is located in intron 5, at the splice-acceptor site, and has been demonstrated to regulate splicing, resulting in isoforms with different enzyme activity [39,55]. Recent data from the literature suggests that genetic variation in *OAS1* (rs10774671) can alter viral replication in human lymphoid tissue and is a risk factor for infection with West Nile virus [39]. In addition, our previous work links this same polymorphism in addition to other *OAS* polymorphisms with variations in rubella vaccine-induced cytokine secretion [14].

Another interesting antiviral gene potentially associated with measles virus-specific immune variations is *ADAR*, which is involved in RNA editing (that substitutes adenosines by inosines) of cellular mRNA and viral dsRNA targets. Our data show evidence for an association of a nonsynonymous SNP (rs2229857/Arg384Lys, in LD with other significant *ADAR* SNPs, $r^2 \geq 0.96$) with measles virus-specific cellular immunity (IFN-γ Elispot responses) in Caucasians ($p = 0.01$, Table 3). Consistent with the current findings, our previous rubella vaccine study demonstrated an increase in rubella-specific IFN-γ responses ($p = 0.021$) with the representation of the minor allele genotype for this *ADAR* polymorphism [14], which further suggests the involvement of this gene/genetic variant in immune response variations after vaccination. In addition, other regulatory and intronic SNPs within the same gene were associated at the genotype and haplotype level with variations in measles-specific cellular immunity, particularly in the Caucasian group (haplotype global p-value = 0.017, Table 4), implying cooperative effects of multiple SNPs in the genetic regulation of the immune outcome. This is in concert with the identification of ADAR as a critical determinant of local and systemic inflammatory responses through RNA editing and modulation of protein production [56]. It is important, however, to note that we did not find similarities between the genes/genetic variants associated with measles-specific IFN-γ Elispot responses and IFN-γ cytokine secretion in our analyses in Caucasians, and while the genetic associations with secreted IFN-γ remained significant after adjusting for FDR, none of the SNPs associated with IFN-γ Elispot responses remained significant after adjustment. Both our IFN-γ assays quantify IFN-γ responses, but as reported previously these assays do not correlate well with each other [57]. IFN-γ Elispot measures the number of cytokine-producing cells, while the IFN-γ ELISA measures the cytokine protein concentration released in the culture supernatant by virus-stimulated cells. We speculate that the lack of correlation (or weak correlation) between the two assays [57] is likely the main reason for the different genetic associations found in our analyses for these two immune outcomes.

Our findings point to the plausible role of several interrogated innate immunity genes in the observed inter-individual variations following measles vaccination, although some of the observations should be interpreted with caution since many of the single-SNP associations did not remain significant after adjusting for FDR at $q < 0.20$ [38].

The identified genes influencing vaccine-induced measles immunity are all interconnected components of the innate antiviral responses targeting viral nucleic acids. Viral nucleic acids stimulate the OAS-RNase L pathway resulting in RNA degradation. Viral RNA is also targeted by ADAR, which deaminates viral replication intermediates. In addition, viral RNA activates RNA helicase-like receptors, including RIG-I, to initiate signaling and transcription of IFNs (through IRFs), which feed back through their receptors to increase the expression of antiviral proteins, thus augmenting the antiviral response [10,58]. Hence, our findings imply that key genetic variants/genes involved in the initial antiviral response to viral nucleic acids are modulating immune responses after vaccination with a live viral vaccine, likely due to alterations in viral sensing and/or direct antiviral activity that restricts viral replication and antigen load/antigenic stimulation. Although some of the genes such as *DDX58*, *ADAR* and *OAS1* (and even genetic variants: *OAS1* rs10774671) were found to be associated with variations in both rubella vaccine [14–16] and measles vaccine-induced immune responses in our studies, most of the identified genetic variants and association patterns appear to be virus-specific, possibly due to differences between viruses with respect to their ability to induce and/or counter some of the involved proteins and antiviral pathways [11–13,58].

A major strength of our study is the use of a relatively large racially diverse cohort of healthy vaccines after two doses of MMR vaccine, with extensive demographic and clinical information available, and no known contact with wild type measles virus infection. This allowed us to probe for race-specific associations (in the two most prevalent racial groups, Caucasians and African-Americans) with vaccine-induced immunity outcomes in our study cohort. A novel aspect of the present study is the comprehensive list of genetic variants, genotyped across 12 key antiviral genes (never before studied in the context of measles vaccine response heterogeneity) and correlations with clinically relevant vaccine-induced immune outcomes, such as neutralizing antibody levels.

We recognize that there is a real possibility that some of the reported associations reflect false–positive results, particularly in the smaller sample sizes (and reduced power) available in our race-specific analysis. In our work we choose to report the findings for the two most prevalent racial groups (Caucasians and

African-Americans), separately, as the allele frequencies can vary considerably between racial and ethnic groups and thus can confound the results. Importantly, most of the genes/SNPs and genetic association patterns identified in our study were different between the Caucasian and African-American racial groups we studied, which is not surprising given the differences in allele frequencies for immune response genes reported for these two races [59], as well as the differences in allele/haplotype frequencies observed for the two groups in our study. It is plausible that different genetic polymorphisms would be important in other populations, such as African children, and our findings from a cohort of older children in Minnesota (an area with high vaccination coverage) may not apply to other areas of the world (with low vaccination coverage) where mainly younger children of different race/ethnicity contract the disease.

We also acknowledge the relatively large number of comparisons in our analyses and addressed the multiple testing issues by adjusting for FDR and supplementing the *p*-values with corresponding *q*-values. After correction for FDR, 15 SNPs (out of 32 reported single-SNP associations at the level $p \leq 0.01$; 11 SNPs in Caucasians and 4 SNPs in African-Americans) still remained significant at the *q*-value < 0.20 [38]. As this is the first study assessing polymorphisms in antiviral genes and their possible effect on measles vaccine-induced immunity in a race-specific manner, we chose to also use the less stringent *q*-value cutoff value of 0.5 (roughly corresponding to *p*-values ≤ 0.01 for single-SNP associations) believing that the risk of false negatives outweighs that of false positives.

Nevertheless, the high biological plausibility for some of the genetic variants, the haplotype-level associations, the observed allele dose-related relationships and cross-regulation of different immune outcomes by the same genetic variants, and considerable effect on immune outcome measures, increase our confidence in the reported findings. Follow-up replication and function-based studies are planned to validate and extend our results, and increase our understanding of the mechanisms, involved in immune response variations after measles vaccination. This will potentially inform the development of new and/or improved vaccines and support a novel paradigm of vaccine development, a concept we have called vaccinomics [9].

Taken together, the increasing evidence for the role of novel innate immunity genes (such as *DDX58*/*RIG-I*, *OAS* and *ADAR*), in the regulation of measles vaccine adaptive immunity will likely open new avenues for designing better vaccines and improved vaccination strategies.

Acknowledgements

We thank the parents and children who participated in our studies and the Mayo Vaccine Research Group nurses for subject recruitment. We thank the Mayo Vaccine Research Group laboratory personnel for technical help with the assays and Matthew J. Phan and Caroline Vitse for assistance in preparing the manuscript. We thank also Megan O'Byrne for her contribution to statistical analyses and Rick Kennedy for the useful discussions. We thank David Rider and Ying Li for developing the SNP selection algorithm, and Julie M. Cunningham and the Mayo Advanced Genomic Technology Center for assistance with genotyping. Abstract Genetic factors importantly contribute to migraine. However, unlike for rare monogenic forms of migraine, approaches to identify genes for common forms of migraine have been of limited success. Candidate gene association studies were often negative and positive results were often not replicated or replication failed. Further, the significance of positive results from linkage studies remains unclear owing to the inability to pinpoint the genes under the peaks that may be involved in migraine. Problems hampering these studies include limited sample sizes, methods of migraine ascertainment, and the heterogeneous clinical phenotype. Three genome-wide association studies are available now and have successfully identified four new genetic variants associated with migraine. One new variant (rs1835740) modulates glutamate homeostasis, thus integrates well with current concepts of neurotransmitter disturbances. This variant may be more specific for severe forms of migraine such as migraine with aura than migraine without aura. Another variant (rs11172113) implicates the lipoprotein receptor LRP1, which may interact with neuronal glutamate receptors, thus also providing a link to the glutamate pathway. In contrast, rs10166942 is in close proximity to *TRPM8*, which codes for a cold and pain sensor. For the first time this links a gene explicitly implicated in pain related pathways to migraine. The potential function of the fourth variant rs2651899 (*PRDM16*) in migraine is unclear. All these variants only confer a small to moderate change in risk for migraine, which concurs with migraine being a heterogeneous disorder. Ongoing large international collaborations will likely identify additional gene variants for migraine.

Introduction

Migraine is a common neurological disorder affecting between 10 and 20% of the population [1]. The clinical presentation is heterogeneous and includes recurrent headache attacks, associated symptoms of vegetative disturbance, and hypersensitivity of various functional systems of the nervous system [1, 2]. About one-third of migraineurs further experience transient neurological symptoms mostly involving the visual system prior to or during a migraine attack, which are known as migraine aura [2]. The International Headache Society (IHS) has established gold-standard criteria for the diagnosis of migraine [3]. While migraines with aura (MA) and without aura (MO) are the most common forms, the IHS also acknowledges, for example, certain forms lacking one diagnostic criterion as probable migraine as well as rare familial monogenetic forms.

Heredity has been shown to play an important role in migraine pathogenesis. About 50% of affected individuals have a first-degree relative also suffering from migraine [4–6]. In addition, family and twin studies support the idea of MO and MA being different phenotypes of the same entity, with a heritability ranging from 33 to 57% [5, 7, 8].

The broad clinical spectrum of migraine and the results from heritability studies have posted a challenge to the

understanding of the underlying pathophysiology and molecular genetics. For example, it is difficult to find a pathophysiological link between a headache, which is not symptomatic, and symptoms like nausea, photophobia, or hypotension. In addition, it is unclear if some of the clinical symptoms are more genetically determined and some are more environmentally determined. On the contrary, dissecting the migraine phenotype into endophenotypes has offered opportunities to better understand the pathophysiological processes involved, facilitating the formulation of hypotheses for genetic studies. For example, symptoms like yawning (premonitory phase) and nausea (premonitory and headache phase) point toward an involvement of dopamine and have entailed genetic association studies of variants in genes involved in dopamine metabolism [9]. Another approach was to utilize epidemiological data for hypothesis generation. The three- to fourfold higher prevalence of migraine among women than men [10] as well as attacks following a menstrual cycle pattern [11] suggested an involvement of sex hormones and led to the investigation of genetic variants in sex hormone receptor genes [12]. Aware of the limitations of these approaches, methods free of assumptions have been employed mining the genome for associations with the migraine phenotype or certain migraine symptoms. These include linkage studies and genome-wide association studies (GWAS). In contrast to all approaches focusing on common forms of migraine, investigations in rare familial forms of migraine, presenting with a well circumscribed aura in the form of a hemiparesis/hemiplegia (familial hemiplegic migraine, FHM), have been more successful in identifying underlying genetic causes [13–15].

This manuscript does not aim at providing a complete overview of genetic studies in migraine; this has comprehensively been done recently [16, 17]. This manuscript will provide examples for different approaches used in migraine genetics and then focus on results from the recently published GWASs.

Familial hemiplegic migraine (FHM)

FHM is a rare, but severe form of migraine displaying an autosomal dominant mode of transmission. The main characteristic of FHM is a prolonged aura in the form of a hemiparesis/hemiplegia presenting with the migraine headache. FHM belongs to the group of channelopathies and multiple genetic variants in three different genes coding for neuronal ion channels have been identified as causative. These genetic variants perturb the activity of the channels, thus increasing neuronal excitability. In FHM type 1 the affected gene is *CACNA1A* (chromosome 19p13), coding for a P/Q calcium channel [15], in FHM type 2 the *ATP1A2* gene (chromosome 1q23) is affected, encoding a subunit of the Na^+/K^+-ATPase [13], and FHM type 3 is caused by variants in the *SCN1A* gene (chromosome 2q24), coding for a sodium channel [14]. However, patients with FHM only constitute a very small proportion of all migraineurs and there is little evidence, that the identified genes play a major role in common forms of migraine [18]. This may also suggest that the ion channel genes are only important for the aura and not the migraine per se, since, in particular, the *CACNA1A* gene is also implicated in other neurological disorders not associated with migraine including episodic ataxia type 2 and spinocerebellar ataxia type 6.

Candidate gene approaches

Candidate gene approaches have been a popular tool in studying migraine genetics. Genes investigated are, for example, implicated in serotonin and dopamine metabolism, neurogenic inflammation, vascular function, and hormone regulation.

Migraine is viewed as an inherited brain disorder, characterized by neurotransmitter imbalances that lead to neuronal dysfunctions [19]. The serotonergic system plays an important role and alterations in serotonin metabolism and in the processing of central serotonin-mediated responses are typical features among migraineurs [20]. Following axonal release serotonin (5-HT) is rapidly taken up again by the presynaptic serotonin transporter SLC6A4 (5-HTT) [21]. An insertion/deletion polymorphism in the promoter region of the SLC6A4 gene, termed 5-HTTLPR [22, 23] has functional impact on the synaptic clearing of serotonin [24]. Ten studies in different populations have investigated the association between the *5-HTTLPR* gene and migraine among Europeans and Asians [25]. Pooled analyses did not find an overall association; however, there was some suggestion that gender and migraine aura status may have modifying roles among Europeans.

Another neurotransmitter implicated in migraine pathogenesis is dopamine. Symptoms like yawning in the premonitory phase and nausea in both the premonitory and headache phase are ascribed to dopamine [26]. There is also evidence from other pain disorders that dopamine plays a role in central pain [27]. Further support for a role of dopamine in migraine comes from studies showing that anti-dopaminergic drugs exert beneficial effects, when administered during migraine attacks and from experimental work showing that dopamine modulates the neuronal firing rate in the trigeminocervical complex [9]. Genetic association studies have mostly investigated variants in dopamine receptor genes and the dopamine beta-hydroxylase gene; however, study results are conflicting and the significance of these variants in migraine remains unclear.

A “neurogenic inflammation” appears to be a key mechanism in causing the migraine headache by activating the trigeminal system [28]. Tumor necrosis factor-alpha (TNF-alpha) is an important inflammatory cytokine and modulator of immune responses. Its role in migraine has been postulated based on reports of TNF-alpha concentration changes in serum [29–31] and urine [32] among migraineurs, as well as findings that TNF-alpha can stimulate transcription of calcitonin gene-related peptide (CGRP), which is pivotal in migraine pathophysiology [33]. Variants in the genes coding for TNF-alpha and the closely related TNF-beta have been shown to modulate cytokine levels of TNF-alpha and TNF-beta [34, 35] prompting investigations of various polymorphisms in these genes with respect to their role in migraine. Among the ten studies investigating variants in these genes, the best evidence is available for the *TNF-alpha* -308G>A and *TNF-beta* 252A>G polymorphisms. Pooled analyses did not indicate an overall association with migraine [36]. While subgroup analyses suggested that associations may differ among populations of non-Caucasian origin, these findings only stem from few studies.

Migraine prevalence is three- to fourfold higher in women than men [10]. Further, some women suffer from migraine attacks presenting at specific times during the menstrual cycle or experience changing patterns of attacks during pregnancy or after menopause [11, 37]. Finally, changes in estrogen levels can trigger migraine attacks [11, 37]. These findings have prompted studies investigating variants in genes coding for proteins in sex hormone receptor pathways and metabolism among migraineurs. Pooled analyses of the available studies suggest that the estrogen receptor-1 gene (*ESR-1*) 594 G>A and 325 C>G polymorphisms can modify the risk for migraine, a finding that does not differ between MA and MO [12]. In contrast, the *ESR-1* Pvu II C>T polymorphism and the progesterone receptor (*PGR*) PROGINS insert polymorphism do not appear to be associated with migraine.

The vasculature appears to play a special role in migraine. For example, migraineurs carry an approximately twofold increased risk for ischemic stroke compared to non-migraineurs [38], some vasculopathies are frequently observed among migraineurs such as livedo reticularis [39] and Sneddon’s syndrome [40], and altered vascular reactivity can be found among young migraineurs even in the absence of other disorders [41]. These findings may be linked to oxidative stress causing endothelial dysfunction [42]. Specifically, certain gene variants in the methylenetetrahydrofolate reductase gene (*MTHFR* 677C>T polymorphism) and angiotensin-converting enzyme gene (*ACE* D/I polymorphism) appear to importantly contribute to the vascular oxidative stress response [42]. Consequently, an association between the *MTHFR* 677C>T and *ACE* D/I polymorphisms with migraine has been suggested [42]. Both are functional variants. The *MTHFR* 677TT genotype impairs enzyme activity and carriers have increased homocysteine levels. Carriers of the *ACE* II genotype have ACE plasma levels half that of DD subjects, with ID subjects having intermediate levels. Association studies investigating the role of these variants in migraine were controversial. Pooled analyses of 13 studies indicated that the *MTHFR* 677TT genotype was associated with a 48% increased risk for MA (pooled odds ratio [OR] = 1.48, 95% confidence interval [CI] 1.02–2.13), but not MO [43]. In contrast, pooled results from nine studies indicated that the *ACE* II genotype was associated with a reduced risk for MA (pooled OR = 0.71, 95% CI 0.55–0.93) and MO (pooled OR = 0.84, 95% CI 0.70–0.99) [43].

Genome-wide approaches

In contrast to candidate gene association studies, genome-wide approaches have been employed to identify potential new chromosomal regions or genes that may associate with migraine, migraine subtypes, or migraine features. These are basically data mining techniques screening a part or the whole genome. The two main methods employed are linkage analyses that study pedigrees of migraineurs and GWAS that investigate large populations of migraineurs and non-migraineurs.

Linkage studies

Linkage analyses have identified several genetic loci for overall migraine, MA, and MO. However, the underlying genes from these chromosomal regions that may plausibly alter risk of migraine have not yet been identified. Overall migraine has been linked to chromosomes Xq24-28 [44], 6p12.2-21.1 [45], 19p13 [46], and 1q31 [47]; MA to 4q24 [48], 9q21-q22 [49], 11q24 [50], and 15q11-13 [51]; and MO to 14q21.1-22.3 [52], and 4q21 [53].

Alternative phenotyping methods

Only two independent linkage studies from Iceland and Finland describe an overlapping gene locus on chromosome 4 [48, 53]. However, the other studies have reported many different loci, which is likely a reflection of the genetic heterogeneity of migraine. The heterogeneous migraine phenotype with a broad spectrum poses a particular challenge to genetic studies, which may in part explain the genetic heterogeneity observed. Hence, more clearly defined individual features of migraine (“endophenotypes”) may help to more consistently identify genetic loci or genes involved in migraine [54]. For example, employing trait component analysis and latent class analysis has successfully linked certain chromosomal regions to pulsating pain, phono-/photophobia, nausea, and age at onset of migraine [44, 55, 56].

Genome-wide association studies

The first GWAS in migraine was published by the International Headache Genetics Consortium (IHGC) in 2010 [57] (Table 1). This was a two-stage association study involving seven clinic-based case collections. In the discovery stage 2,731 migraineurs all suffering from MA, recruited from clinics in Finland, Germany, and the Netherlands, were compared with 10,747 population-based controls from the same countries. In the replication stage an additional 3,202 cases from clinics in Denmark, the Netherlands, and Germany as well as from the general population in Iceland were available and compared to 40,062 population-based controls. Patients used for replication suffered either from MA or MO. Diagnoses were made by headache experts using a combination of questionnaires and direct interviews based on the 2004 IHS diagnostic criteria [3]. The following diagnostic subgroups were analyzed: overall migraine, MA only, MA and MO, and MO only.

In the discovery stage, 429,912 genetic variants were genotyped in cases and controls utilizing an Illumina array. Considering a genome-wide significance threshold of $p \leq 5 \times 10^{-8}$, only one single nucleotide polymorphism (SNP; rs1835740) was significantly associated with overall migraine. When using a more liberal threshold of $p \leq 5 \times 10^{-5}$ eleven SNPs were associated with migraine. The minor allele of rs1835740 was associated with an increased risk for migraine (OR = 1.23, 95% CI 1.15–1.32, $p = 5.38 \times 10^{-9}$). The population attributable risk for this marker was estimated to be 10.7%. Replication of the association at rs1835740 was successful and the meta-analysis of results from all seven case–control samples indicated an 18% increased risk for overall migraine (OR = 1.18, 95% CI 1.13–1.24, $p = 1.69 \times 10^{-11}$). In subgroup analyses, the effects were stronger for patients with MA than in those suffering from MO.

Findings from this GWAS lend support for a role of glutamate in the pathophysiology of migraine, in particular MA. rs1835740 is located between the genes *MTDH* and *PGCP*, which are involved in glutamate homeostasis. The study authors have also shown that the minor allele of rs1835740 increases the expression levels of *MTDH* [57]. Further, previous studies in astrocytes have indicated that *MTDH* downregulates *SLC1A2*, which codes for the major glutamate transporter in the brain. This may lead to an increase in the extracellular concentration of glutamate, the major excitatory transmitter in the central nervous system. Glutamate plays a role in trigeminovascular pain processing [58] and may modulate the threshold for cortical spreading depression [59], the putative biological correlate of the aura [60].

In addition to rs1835740, eleven SNPs were associated with migraine with $p \leq 5 \times 10^{-5}$ (Table 1). Although missing genome-wide significance, these SNPs may have potential implications for migraine. Nine of these are located within or close to known genes including *SMYD3*, *INSIG2*, *TRPM8*, *MYLK4*, *ZNF311*, *SGCZ*, *NAV2*, *COG3*, and *AQP9*.

The second GWAS was performed by the Dutch-Icelandic (DICE) migraine genetics consortium [61] (Table 1). In the discovery stage, five Dutch and one Icelandic population-based cohorts with 2,446 migraineurs and 8,534 non-migraineurs were investigated. The replication samples derived from two population-based Dutch cohorts and one Australian Twin study totaling 2,957 migraineurs and 5,774 non-migraineurs. Migraine ascertainment in the discovery cohorts was primarily by means of questionnaires, and genotyping was performed utilizing a variety of genotyping platforms. No SNP was associated with migraine at the genome-wide level, 32 SNPs were associated with migraine at $p < 10^{-5}$. The best association was seen for rs9908234 ($p = 8.00 \times 10^{-8}$), which is located in the nerve growth factor (NGF) gene. However, neither this variant nor 18 other chosen variants out of the 32 variants showed associations in the replication cohorts. In a further step, the authors explored associations of previously identified candidate gene variants for migraine with migraine in the pooled discovery dataset. None of the candidates was associated with migraine; however, in gene-based analyses there was modest support for an association of *MTDH*, implicated in the previous GWAS [57], with migraine. Among the reasons potentially explaining the inability to replicate findings from the discovery cohorts are usage of different genotyping platforms, methods of migraine ascertainment, and a lack of power, despite the efforts of bringing together many cohorts.

The third GWAS was also performed to identify common genetic variants for migraine at the population level [62] (Table 1). The study included three population-based cohorts and information from the IHGC. The population-based cohorts were the Women’s Genome Health Study (WGHS), the Genetic Epidemiology of Migraine (GEM) study, and the Study of Health in Pomerania (SHIP). Migraine was either self-reported on questionnaires, diagnosed by headache experts or by a combination of both.

[a] Results for overall migraine

Genotyping was performed by Illumina chips (WGHS, IHCG), Affymetrix arrays (SHIP), and iPLEX method from Sequenom (GEM).

The discovery cohort consisted of 23,230 women of European ancestry participating in the WGHS, which is a large population-based cohort in the US. Among those 5,122 women reported migraine, while 18,108 did not. In the genome-wide scan using age-adjusted logistic regression and assuming an additive genetic model, none of the investigated SNPs were associated with migraine at $p < 5 \times 10^{-8}$. However, seven independent genetic loci had at least one SNP with an association of $p < 5 \times 10^{-6}$. From each locus the authors selected the most significant SNP (Table 1). None of these seven SNPs was associated with non-migraine headache. In addition, none of the seven SNPs showed associations with migraine in non-additive models, and no other SNP in the genome-wide scan reached genome-wide significance in non-additive models. Finally, association analysis using imputed genotypes of about 2.6 million SNPs identified the same seven loci as found with the genotyped SNPs.

The seven chosen SNPs were evaluated in GEM (774 migraineurs, 942 non-migraineurs), SHIP (306 migraineurs, 2,260 non-migraineurs), and IHGC (2,748 migraineurs, 10,747 non-migraineurs). The effect estimates for three of the SNPs (rs2651899, rs10166942, rs11172113) pointed in the same direction and were comparable in magnitude in all three replication studies as in the WGHS. In the next step a meta-analysis of results for the seven primary SNPs from all four cohorts was performed using a fixed-effects model, since there was no strong evidence of heterogeneity. All three SNPs identified from the replication cohorts based on concordance in direction and magnitude of association were associated with migraine at the genome-wide level (rs2651899: OR = 1.11, 95% CI 1.07–1.15, $p = 3.8 \times 10^{-9}$; rs10166942: OR = 0.85, 95% CI 0.82–0.89, $p = 5.5 \times 10^{-12}$; rs11172113: OR = 0.90, 95% CI 0.87–0.93, $p = 4.3 \times 10^{-9}$). rs2651899 at 1p36.32 is located within the first intron of *PRDM16*, rs10166942 at 2q37 is very close to the transcription start site for *TRPM8*, and rs11172113 at 12q13.3 is in the first intron of *LRP1*. Interestingly *TRPM8* was associated with migraine in the first IHGC GWAS at the sub-genome-wide level [57].

Gender-stratified analyses suggested that the association seen at rs10166942 (*TRPM8*) may be specific for women (meta-regression on gender $p = 0.004$). However, this potential differential association did not appear to be related to genetic variants in the *ESR1* gene, as there was no interaction between rs10166942 (*TRPM8*) and *ESR1* variants. Further investigations looking at potential differences according to migraine aura status and features (for example, unilateral pain location, pulsating pain quality, photophobia, etc.) did not suggest that the associations seen for any of the three variants differed by the presence or the absence of aura or any of the features. Finally, the associations seen for rs2651899 (*PRDM16*) and rs10166942 (*TRPM8*), but not rs11172113 (*LRP1*), were significantly associated with migraine compared to non-migraine headache, underlining the specificity of these variants for migraine.

TRPM8 codes for a cold and cold-induced burning pain sensor [63] which is primarily expressed in sensory neurons and the dorsal root ganglion [64]. *TRPM8* is investigated as a target in animal models of neuropathic pain [65]. Since migraine and neuropathic pain share some characteristics [66], a role for *TRPM8* in migraine as well as a link between both pain syndromes is plausible.

LRP1 belongs to the lipoprotein receptor family and is ubiquitously expressed [67]. LRP1 and NMDA glutamate receptors co-localize on neurons and they interact. This is particularly interesting since the previous GWAS by the IHGC has identified a genetic variant involved in glutamate homeostasis [57]. Both findings underline the role of glutamate in migraine pathophysiology and integrate well with pharmacological approaches targeting glutamate receptors for migraine treatment [58].

A role for *PRDM16* in migraine is unknown. Originally identified at a chromosomal breakpoint associated with myelodysplastic syndrome and leukemia [68], more recent research has focused on its role in brown fat development [69].

Implications

Endeavors to decipher the genetics of migraine have been successful with respect to FHM; however, there is ongoing debate about whether the genes involved (all coding for ion channels) are specific for migraine headache, the accompanying hemiplegic aura, or possibly for both. In contrast, attempts for common forms of migraine, although multifold, were often ambiguous. Positive results from candidate gene association studies have mostly not been robust, with the exception, for example, for the *MTHFR* 677C<T polymorphism, which shows an association with migraine in pooled analysis of the available studies. Many other genetic variants were not associated with migraine or replication of positive results is either missing or failed. Linkage studies produced some encouraging results, but it remains unclear which genes under the linkage peaks may be important for migraine. Reasons hampering an unequivocal success of previous studies include limited sample size, heterogeneity of the migraine phenotype as well as study design and conduct.

Migraine GWASs have overcome some of these drawbacks and advanced our understanding of migraine genetics with the following implications. First, available GWASs have identified four new genetic variants that are associated with migraine with genome-wide significance and none of the implicated genes has been a candidate in previous genetic studies. Second, the role for three of the variants may plausibly be integrated with current concepts of migraine pathophysiology. rs1835740 modulates glutamate homeostasis [57] and rs11172113 (*LRP1*) [62] may also impact glutamate pathways through interaction of LRP1 receptors with NMDA glutamate receptors. Further, the association at rs10166942 (*TRPM8*) for the first time implicates a gene in a pain related pathway in migraine. Third, the available results are compatible with shared pathophysiology among common forms of migraine, since associations for rs2651899 (*PRDM16*), rs10166942 (*TRPM8*), and rs11172113 (*LRP1*) did not differ for MA and MO [62]. Fourth, the results also suggest differences between population-based and clinic-based forms of migraine. While rs2651899 (*PRDM16*), rs10166942 (*TRPM8*), and rs11172113 (*LRP1*) appear most important for common migraine (i.e., at the population level) [62], rs1835740 may play the major role in more severe forms of migraine (i.e., clinic-based populations) [57]. This agrees with the fact that virtually all migraineurs in the IHGC study suffered from MA [57], which is often considered more severe than MO. However, the association of rs1835740 with MA may also underline the importance of glutamate for the aura phenotype among migraineurs. Finally, the effect estimates indicate that each of the variants only confers a small to moderate change in risk for migraine (Table 1). This agrees with migraine being a heterogeneous disorder, where many gene variants work together to produce the migraine phenotype.

Outlook

Despite enormous efforts, the published GWASs can “only” claim to have identified four genetic variants to be associated with migraine. This number appears small. However, it is imperative to keep in mind the broad clinical phenotype of migraine, which complicates the identification of genetic variants. In addition, we must consider that the implicated genes are both new, replicated in independent samples, and at the same time plausibly involved in migraine pathophysiology.

Additional approaches in studying migraine genetics include focusing on endophenotypes of migraine and investigating larger numbers of migraineurs and non-migraineurs. Trait component analysis and latent class analysis have been used previously [44, 55, 56], and may also be promising approaches for future GWASs. Further, large international collaborations are ongoing aiming at combining genome-wide genetic data on migraine to increase the power to identify additional genetic variants in migraine. Additional variants will likely be identified. Finally, we need to understand that GWASs “only” investigate hundreds of thousands of common and known gene variants. However, there is ample space in the genome that is not investigated. Hence, variants identified may only be markers for migraine, which are in linkage disequilibrium with the causative variants. Further, there may be areas in the genome that are not well represented on the GWAS platforms, but which may plausibly harbor variants involved in migraine pathophysiology. In both scenarios it may be useful to utilize DNA sequencing methods to investigate certain genes or chromosomal regions to obtain a complete map of all variants, including rare variants, in these regions. This may facilitate the discovery of the single best marker in a region or even identify new variants. Considering the large number of DNA base pairs to be sequenced as well as the large number of individuals that may have to investigated, high-throughput sequencing methods may have to be used. However, the limitations associated with each of the available platforms need to be considered and the technology used must be tailored to the specific projects.

Conflict of interest Dr. Schürks has received an investigator-initiated research grant from the Migraine Research Foundation. He has received honoraria from L.E.K. Consulting for telephone surveys and from the American Academy of Neurology for educational material. He is a full-time employee of Bayer HealthCare Germany Pharmaceuticals since August 2011.

Genomic epidemiology of syphilis in England: a population-based study

Mathew A Beale, Louise Thorn, Michelle J Cole, Rachel Pitt, Hannah Charles, Michael Ewens, Patrick French, Malcolm Guiver, Emma E Page, Erasmus Smit, Jaime H Vera, Katy Sinka, Gwenda Hughes, Michael Marks, Helen Fifer, Nicholas R Thomson**

Summary

Background Syphilis is a sexually transmitted bacterial infection caused by *Treponema pallidum* subspecies *pallidum*. Since 2012, syphilis rates have risen dramatically in many high-income countries, including England. Although this increase in syphilis prevalence is known to be associated with high-risk sexual activity in gay, bisexual, and other men who have sex with men (GBMSM), cases are rising in heterosexual men and women. The transmission dynamics within and between sexual networks of GBMSM and heterosexual people are not well understood. We aimed to investigate if whole genome sequencing could be used to supplement or enhance epidemiological insights around syphilis transmission.

Methods We linked national patient demographic, geospatial, and behavioural metadata to whole *T pallidum* genome sequences previously generated from patient samples collected from across England between Jan 1, 2012, and Oct 31, 2018, and performed detailed phylogenomic analyses.

Findings Of 497 English samples submitted for sequencing, we recovered 240 genomes (198 from the UK Health Security Agency reference laboratory and 42 from other laboratories). Three duplicate samples (same patient and collection date) were included in the main phylogenies, but removed from further analyses of English populations, leaving 237 genomes. 220 (92·8%) of 237 samples were from men, nine (3·8%) were from women, and eight (3·4%) were of unknown gender. Samples were mostly from London (n=118 [49·8%]), followed by southeast England (n=29 [12·2%]), northeast England (n=24 [10·1%]), and southwest England (n=15 [6·3%]). 180 (76·0%) of 237 genomes came from GBMSM, compared with 25 (10·5%) from those identifying as men who have sex with women, 15 (6·3%) from men with unrecorded sexual orientation, nine (3·8%) from those identifying as women who have sex with men, and eight (3·4%) from people of unknown gender and sexual orientation. Phylogenomic analysis and clustering revealed two dominant *T pallidum* sublineages in England. Sublineage 1 was found throughout England and across all patient groups, whereas sublineage 14 occurred predominantly in GBMSM older than 34 years and was absent from samples sequenced from the north of England. These different spatiotemporal trends, linked to demography or behaviour in the dominant sublineages, suggest they represent different sexual networks. By focusing on different regions of England we were able to distinguish a local heterosexual transmission cluster from a background of transmission in GBMSM.

Interpretation These findings show that, despite extremely close genetic relationships between *T pallidum* genomes globally, genomics can still be used to identify putative transmission clusters for epidemiological follow-up. This could be of value for deconvoluting putative outbreaks and for informing public health interventions.

Introduction

Syphilis is a sexually transmitted infection (STI) caused by the bacterium *Treponema pallidum* subspecies *pallidum* (hereafter referred to as *T pallidum*). Syphilis rates have been rising in many high-income countries since the beginning of the 21st century.[1–4] In England, new diagnoses of early syphilis (primary, secondary, and early latent) rose from 3011 in 2012 (5·6 per 100 000 population) to 8011 in 2019 (14·2 per 100 000 population).[3] This increase has primarily been associated with gay, bisexual, and other men who have sex with men (GBMSM) engaging in high-risk sexual behaviours.[2,3,5] However, cases of syphilis in heterosexual men and women have also risen, raising concerns about infection during pregnancy and risks of vertical transmission leading to congenital syphilis.[6,7] Between 2016 and 2019, annual syphilis diagnoses increased by 53% (from 660 to 1012) in men who identify as heterosexual and have sex with women (MSW) and 108% (from 294 to 614) in women who identify as heterosexual and have sex with men (WSM). 24 cases of congenital syphilis were identified in England between 2015 and 2020, 15 of which were in children born to mothers who tested negative at first trimester

Research in context

Evidence before this study

Detailed phylogenomic analyses investigating the epidemiology and transmission dynamics of *Treponema pallidum* are challenging due to low bacterial loads in clinical specimens, and difficulty in culturing the bacteria. We searched PubMed from Jan 1, 1998, to Aug 9, 2022, using the search terms "Syphilis" or "*Treponema pallidum*" and "genomic" or "genome(s)" or "sequencing". We found 23 studies describing whole genome sequencing of the *T pallidum* subspecies *pallidum*, of which two used whole genome phylogenies to investigate sexual network epidemiology, with one large study of sexual networks done primarily in Victoria, Australia, which characterised two major circulating sublineages in that setting and putative sexual transmission networks with distinct sexual behavioural characteristics and potential bridging between networks.

Added value of this study

In this study, we linked national surveillance data to *T pallidum* genomes, and characterised the transmission dynamics of syphilis using samples from across the whole of England. Integration of national-level sociodemographic, spatiotemporal, and genomic data allowed the delineation of putative sexual networks at both the national and region levels, and revealed patterns not previously detected using epidemiological or genomic data alone.

Implications of all the available evidence

Our findings are consistent with findings in Australia that indicate that genomics can identify putative sociodemographic transmission clusters. However, in that study, genomic clusters included samples separated by multiple single nucleotide polymorphisms, which could represent several years of evolution. Our study explored the value of linking identical genomes, and highlights that, despite technical constraints, whole genome sequencing can be used to enable outbreak exclusion and identify putative local transmission clusters for epidemiological follow-up.

antenatal screening,[8] indicating they had acquired syphilis later in pregnancy. Some cases were identified in regions across England with increases in syphilis among women and GBMSM, suggesting that overlapping sexual networks might have facilitated wider dissemination.[9]

Although epidemiological surveillance provides insights into the rise in syphilis rates, this is not always sufficient. For example, a group of spatiotemporally clustered cases could represent a single outbreak and chain of transmission, but could also be the result of separate or unrelated transmission networks. Molecular typing methods[10–13] provide one possible way to supplement epidemiological observations by identifying genetically related *T pallidum* strains. However, these methods might not accurately reflect recent evolutionary relationships between strains,[14–16] but instead cluster groups of bacteria that shared a common ancestor decades ago, meaning it would be impossible to accurately delineate strain clusters relevant to epidemiologically useful timelines (usually months to years).

Whole genome sequencing (WGS) has shown there are two co-circulating *T pallidum* lineages globally (Nichols and SS14),[17–19] which can be further divided into 17 sublineages plus singletons.[17] These data showed that *T pallidum* genomes accumulate single nucleotide polymorphisms (SNPs) very slowly, with a median molecular clock rate equivalent to one substitution per genome every 6·9 years (95% highest posterior density 5·9–8·2 years),[17] similar to other studies,[20,21] which means that isolate genomes from strains circulating in the UK can be identical (zero pairwise-SNPs) to those from Canada, Australia, and other countries, and identical genomes were collected an average of 2·5 years apart (range 0–15 years). This genetic homogeneity has been suggested to indicate a global dissemination of *T pallidum* within the past 30 years, driven by a small number of multi-country sublineages,[17] and that genomic approaches might also be of limited value to investigate or resolve epidemiological links between patients with syphilis.

See **Online** for appendix 1

Few studies have combined WGS with patient demographic and sexual behaviour metadata to explore epidemiological trends of *T pallidum*, with studies from Japan[22] and Australia[21] finding discrete genetic clusters associated with GBMSM and heterosexual people. We explored the value of WGS for supplementing existing epidemiological data for understanding transmission at national and regional levels. We combined detailed patient demographic and epidemiological data with WGS of *T pallidum* samples from England to gain insights into the different spatiotemporal and genomic transmission patterns of syphilis affecting GBMSM and heterosexual people.

Methods

Study design and participants

A detailed description of sample collection and patient metadata linkage in this population-based study is provided in appendix 1 (pp 1–2). *T pallidum*-positive genomic DNA samples were retrieved from historical archives (2012–17) held at the UK Health Security Agency (UKHSA, previously Public Health England) STI Reference Laboratory (Colindale, London), and prospectively collected (2016–18) from five laboratories with high syphilis caseloads who do in-house molecular *T pallidum* diagnostic testing (and thus do not usually refer to the UKHSA reference laboratory; Birmingham, Brighton, Leeds, London [Mortimer Market Clinic at Central and North West London NHS Trust], and Manchester).

For samples from UKHSA, patient metadata were obtained by linkage to the national STI surveillance system (Genitourinary Medicine Clinic Activity Dataset [GUMCAD]). For samples prospectively collected from the five non-referring laboratories, patient metadata available from local laboratory information systems was linked to GUMCAD data and integrated into the larger dataset after deduplication (appendix 1 pp 1–2). For comparison between the sequencing dataset and national surveillance rates, we also retrieved summary statistics from GUMCAD data for all patients with syphilis aged 16 years and older in England from 2012 to 2018 (n=50 845).

Ethics and data governance

Ethical approval for all clinical samples was granted by the National Health Service (UK) Health Research Authority and Health and Care Research Wales (UK; 19/HRA/0112) and the London School of Hygiene & Tropical Medicine Observational Research Ethics Committee (16014). Diagnostic samples were identified at UKHSA using internal laboratory information systems. UKHSA has permission to process confidential patient data under regulation 3 (control of patient information) of the UK Health Service Regulations 2002. Information governance advice and ethics approval for this study were granted by the UKHSA Research Ethics and Governance Group. Full details of approvals and pseudonymisation of samples and patient metadata are described in appendix 1 (pp 2–3).

Procedures

WGS of all clinical *T pallidum* samples used in this study has been previously described,[18] and was done directly on the genomic DNA extracts from residual diagnostic samples using the pooled sequence capture method[19] on Illumina HiSeq 4000. Detailed spatiotemporal and sociodemographic metadata retrieved from the national STI surveillance system were linked to the multiple sequence alignments and time-scaled phylogenies generated and validated previously, to maintain consistency (appendix 1 pp 1–5).[17]

Outcomes

The primary outcome was to identify local lineages of *T pallidum* samples and distinguish transmission clusters by location or sexual orientation. A secondary outcome was to investigate rates and distribution of macrolide resistance-conferring alleles among *T pallidum* sublineages.

Statistical analysis

All statistical analyses were done in R, version 4.1.2 (appendix 1 p 5).

Results

Between Jan 1, 2012, and Oct 31, 2018, we identified and submitted 497 samples considered suitable for sequencing, from which we recovered 240 genomes (198 from the UKHSA reference laboratory and 42 from other laboratories; appendix 1 p 9). Three duplicate samples (same patient and collection date) were included in the main phylogenies, but removed from further analyses of English populations, leaving 237 genomes. 220 (92·8%) of 237 samples were from men, nine (3·8%) were from women and eight (3·4%) were of unknown gender. 217 samples were grouped into nine official Public Health Regions; for 18 samples the region was unknown; two samples were referred to English laboratories from elsewhere in the UK (table). Most samples were from London (n=118 [49·8%]), followed by southeast England (n=29 [12·2%]), northeast England (n=24 [10·1%]), and southwest England (n=15 [6·3%]). Analysis of collection dates showed that although we had sequences from most regions throughout the study period, the northwest and Yorkshire and Humber were represented only at the beginning (2012 and 2013) and end (2018) of the timeline.

For more on **GUMCAD** see https://www.gov.uk/guidance/gumcad-sti-surveillance-system

180 (75·9%) of 237 genomes came from GBMSM, compared with 25 (10·5%) from MSW, 15 (6·3%) from men with unrecorded sexual orientation, nine (3·8%) from WSM, and eight (3·4%) from people of unknown gender and sexual orientation (table; appendix 1 p 10). Notably, the most highly represented region (London) had a higher proportion of GBMSM (110 [93%]) compared with the next most highly represented regions (21 [72·4%] from the southeast, 15 [62·5%] from the northeast, and 12 [80·0%] from the southwest). Due to a low number of heterosexual individuals (30 of 195) in the UKHSA dataset, HIV status was restricted to GBMSM to prevent deductive disclosure (the prospectively collected samples included no MSW or WSM living with HIV). 65 (27·4%) of 237 samples in the national genome collection were from people living with HIV and these were distributed across seven of nine regions. In London, which had the highest proportion of GBMSM, 48 (40·7%) patients were living with HIV.

To establish how representative our national genome collection was of syphilis cases in England, we compared the distributions of sociodemographic characteristics of cases in the national genome collection with those from GUMCAD (table). Overall, our national genome collection (n=237) represented 0·5% of all syphilis diagnoses among patients aged 16 years and older in England during the period 2012–18 (n=50 845). Compared with diagnoses reported in GUMCAD, the samples used in the WGS project were broadly representative by age

(Continued from previous column)

Gender categories are based on reported sexual orientation and gender identity, not on behaviours. WGS=whole genome sequencing. GUMCAD=Genitourinary Medicine Clinic Activity Dataset. MSW=men who have sex with women. GBMSM=gay, bisexual, and other men who have sex with men. WSM=women who have sex with men. *All diagnoses: n=33 190; WGS: n=186. †WGS dataset only.

***Table:* Baseline characteristics of WGS and all syphilis diagnoses from GUMCAD in England, 2012–18**

group, region of residence (including London *vs* non-London), and HIV status (GBMSM only). However, a greater proportion of cases in the genome collection were GBMSM (180 [75·9%] of 237 from the WGS project *vs* 33 190 [65·3%] of 50 845 in the general population), with fewer women (nine [3·8%] *vs* 6467 [12·7%]) and MSW (25 [10·5%] *vs* 8978 [17·7%]). The genome collection also had a much higher proportion of primary syphilis cases compared with GUMCAD (114 [81·4%] in the genome collection compared with 14 178 [27·9%] from GUMCAD), largely reflecting the clinical presentation of primary syphilis with ulcers that permit swabbing.

We inferred the presence of macrolide resistance-conferring SNPs in the ribosomal 23S as previously described,[18] and found that 209 (88·2%) of 237 English genome samples carried the A2058G allele, six (2·5%) of 237 had an uncertain or mixed variant call at position 2058, and five (2·1%) of 237 carried the A2059G allele, meaning that only 17 (7·2%) of 237 English *T pallidum* genomes carried a wild type ribosomal 23S gene and were therefore predicted to be sensitive to macrolide antimicrobials.

A whole genome phylogeny was inferred from the 237 English genomes sequenced here, along with 286 global contextual genomes. We clustered all isolates by lineage, sublineage, or into single-linkage SNP clusters.[23] The English genomes were broadly distributed throughout the known *T pallidum* phylogeny (appendix 1 p 11). Referencing previous work by us and others,[17–19] 183 (77·2%) of 237 genomes belonged to the SS14 lineage and 54 (23·8%) belonged to the Nichols lineage. Of the 17 defined global sublineages,[17] eight were present in the UK, along with one singleton (figure 1A–C; appendix 1 p 12). The English samples were dominated by the global sublineages 1 (n=175 [73·8%]) and 14 (n=44 [18·6%]), but two other globally distributed sublineages (five from sublineage 2 and five from sublineage 8) were also detected in the UK (figure 1A, C) as well as two English samples for each of sublineages 3, 6, and 15, and one for sublineage 16.

Linking previously sequenced whole *T pallidum* genomes from English patients to STI surveillance and

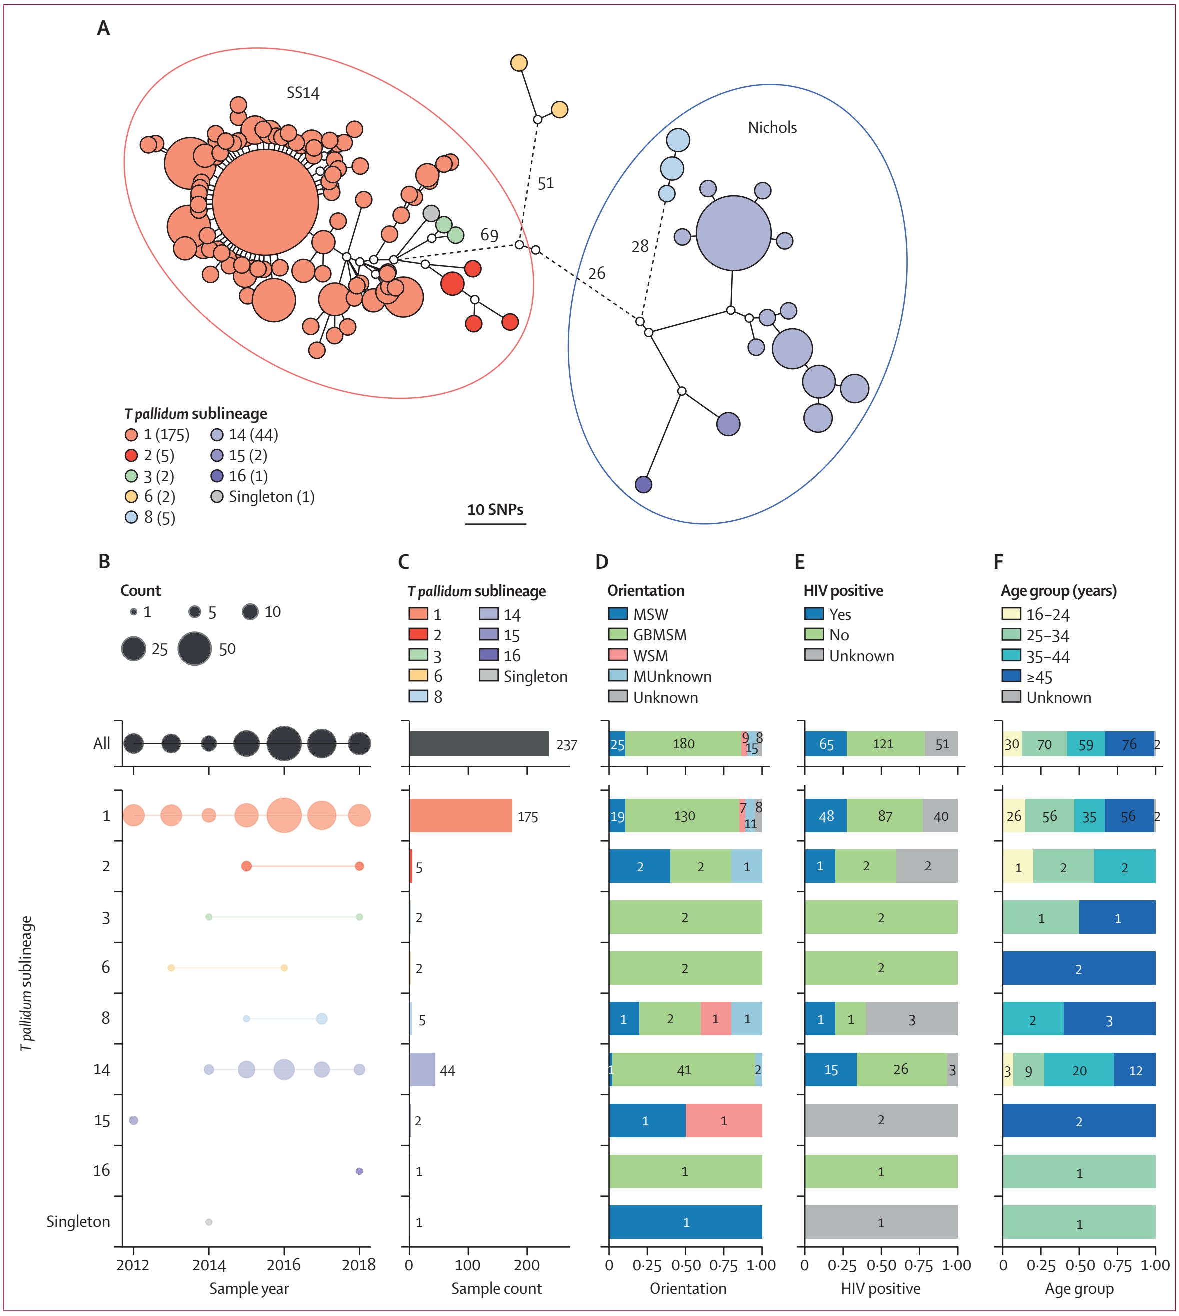

Figure 1: **Population structure of English *Treponema pallidum* genomes according to phylogenetic sublineages and associated patient characteristics**
(A) Minimum spanning tree visualisation of genetic relationships between samples from England. Node size corresponds to the number of identical genome samples in a cluster, and edge length (with number) to the number of substitutions between identical genome sample clusters (where edges were longer than 12 substitutions, these have been shortened; this is indicated by dashed lines). Numbers in parentheses indicate total sample count for each sublineage. Primary lineage (SS14/Nichols) is indicated by encompassing ellipses; sublineage 6 diverges from other *Treponema pallidum* subspecies *pallidum* close to the root, and has previously been classified as Nichols.[18] (B) Samples per collection year per sublineage. (C) Total sample counts per sublineage. Bar plots show proportion of each group. (D) Proportion of each group by sexual orientation. (E) Proportion of each group by HIV status. (F) Proportion of each group by age group (numbers indicate exact sample counts). SNP=single nucleotide polymorphism. MSW=men who have sex with women. GBMSM=gay, bisexual, and other men who have sex with men. WSM=women who have sex with men. MUnknown=men with unrecorded sexual orientation.

laboratory records, we observed that patients infected with the most common sublineage (175 [73·8%] of 237 from sublineage 1) were largely representative of syphilis patients overall, with 130 (74·3%) of 175 classified as GBMSM (figure 1D, appendix 1 p 12) and 91 (52·0%) aged 35 years or older. By contrast, 41 (93·2%) of

44 patients infected with sublineage 14 were GBMSM (1 of 44 MSW, 2 of 44 men with unrecorded sexual orientation), significantly more than would be expected by chance (Fisher's exact p=0·0087). 32 (72·7%) of 44 patients were aged 35 years or older, and 15 (34·1%) were living with HIV. We also found that most patients living with HIV were infected with sublineages 1 or 14, consistent with these lineages being linked to GBMSM networks (figure 1E, appendix 1 p 13). Seven (77·8%) of nine women were infected with *T pallidum* sublineage 1 and no women were infected with sublineage 14 (figure 1D, appendix 1 p 12). We found some rarer sublineage groups contained a greater proportion of heterosexual men and women, with sublineage 8 containing two heterosexual people (one [20·0%] of five WSM, one [20·0%] of five MSW), and sublineage 15 containing two heterosexual people (one [50·0%] of two WSM, one [50·0%] of two MSW) residing in the east of England. Analysis of the genetic relationships indicated that, at least in these two examples, the heterosexual samples were genetically identical to one another but distinct from other samples, falling on terminal nodes of our minimum spanning network (appendix 1 p 12).

To explore sociodemographic patterns of *T pallidum* genome clustering further, we delineated genomes from English patients into 27 distinct clusters of two or more genomes with zero pairwise-SNPs between them (ie, identical at the core genome level; appendix 1 p 14). Given the genetic homogeneity of *T pallidum*, these clusters do not necessarily indicate direct patient-to-patient transmission, but instead provided a means of clustering samples sharing a recent common ancestor. Of the 146 genomes included in these zero-distance genome clusters, 20 were from patients identifying as heterosexual (15 MSW and five WSM). 11 (55·0%) of these 20 patients were part of a cluster containing only other heterosexual individuals. Of the four genome clusters containing WSM, three contained only other heterosexual people and each of these clusters was detected in only a single region. However, the fourth cluster containing a WSM was the largest cluster of identical genomes, comprising 42 samples from sublineage 1, of which 35 patients (83·3%) were GBMSM, compared with three MSW, one WSM, and three with unknown sexual orientation. Therefore, this primarily GBMSM cluster also includes four patients who identify as heterosexual, indicating that there might be some bridging between the populations.

To understand the global context of *T pallidum* from England, we used a Bayesian time-scaled phylogeny of the global dataset (including contextual genomes from 21 other countries, appendix 1 p 15), and examined subtrees for the four most common English sublineages (1, 2, 8, and 14; appendix 1 p 16). Sublineage 1, previously found to be globally disseminated,[17] contained samples from around England and the world; the English samples were polyphyletic and distributed throughout the sublineage 1 phylogeny, with little clustering (appendix 1 p 16), with the exception of a clade predominantly comprising samples from northeast England. Consistent with previous observations, 157 (89·7%) of 175 sublineage 1 strains carried the ribosomal 23S A2058G allele, and were predicted to be resistant to macrolides[17,18] (appendix 1 p 17). As previously described,[17] sublineage 2 comprises two clades, one of which is dominated by North American samples, with the other dominated by samples from China. English samples were found within both clades, with at least three distinct groupings of English strains (appendix 1 p 16), probably indicating multiple recent independent introductions from other countries. By contrast, we found five sublineage 8 samples from England forming a monophyletic subclade along with individual samples from Canada and Australia (appendix 1 p 16). Sublineage 14 represented a major English sublineage, with 44 of 55 sublineage 14 genomes in the global collection coming from England, all of which had the ribosomal 23S A2058G allele. We previously described the contemporaneous appearance of this sublineage in England and Canada in 2013 to 2014,[17] but our time-scaled phylogeny shows two clades within sublineage 14, both of which have median time to most recent common ancestors (1999 and 2006) predating the first detection in our dataset, suggesting this sublineage had been circulating in England for some time (appendix 1 p 16).

We examined the geographical distribution of types in England and found that both the SS14 and Nichols lineages were co-circulating in London and throughout south and central England (figure 2A, E). However, we found only the SS14 lineage in the three most northerly regions (northeast, northwest, Yorkshire and Humber). Examination of *T pallidum* sublineage distributions indicated that sublineage 1 (SS14 lineage) was present in all regions (and represented the only sublineage present in the three northern regions), while sublineage 14 (Nichols lineage) was co-circulating with sublineage 1 in London, the south, and central England but not in northern England (figure 2B, F). There were 35 samples from the three northerly regions, of which 17 (48·6%) were collected after the first detected appearance of sublineage 14 in 2014, coinciding with an increase in national syphilis rates.[24] From 2014 to 2018, the prevalence of sublineage 14 within the national genome collection was 22% (44 of 197). Under an assumption of even sample coverage and sublineage distributions, we could reasonably expect four samples (95% CI 1–7, p=0·022 for zero under a Poisson distribution) to be found in the northern regions, and the absence suggests regional strain distribution is not homogenous.

Apart from the three northern regions and the West Midlands (which contained only sublineages 1 and 14), all other regions contained at least three sublineages (range 3–7). 118 (49·7%) of 237 samples were from

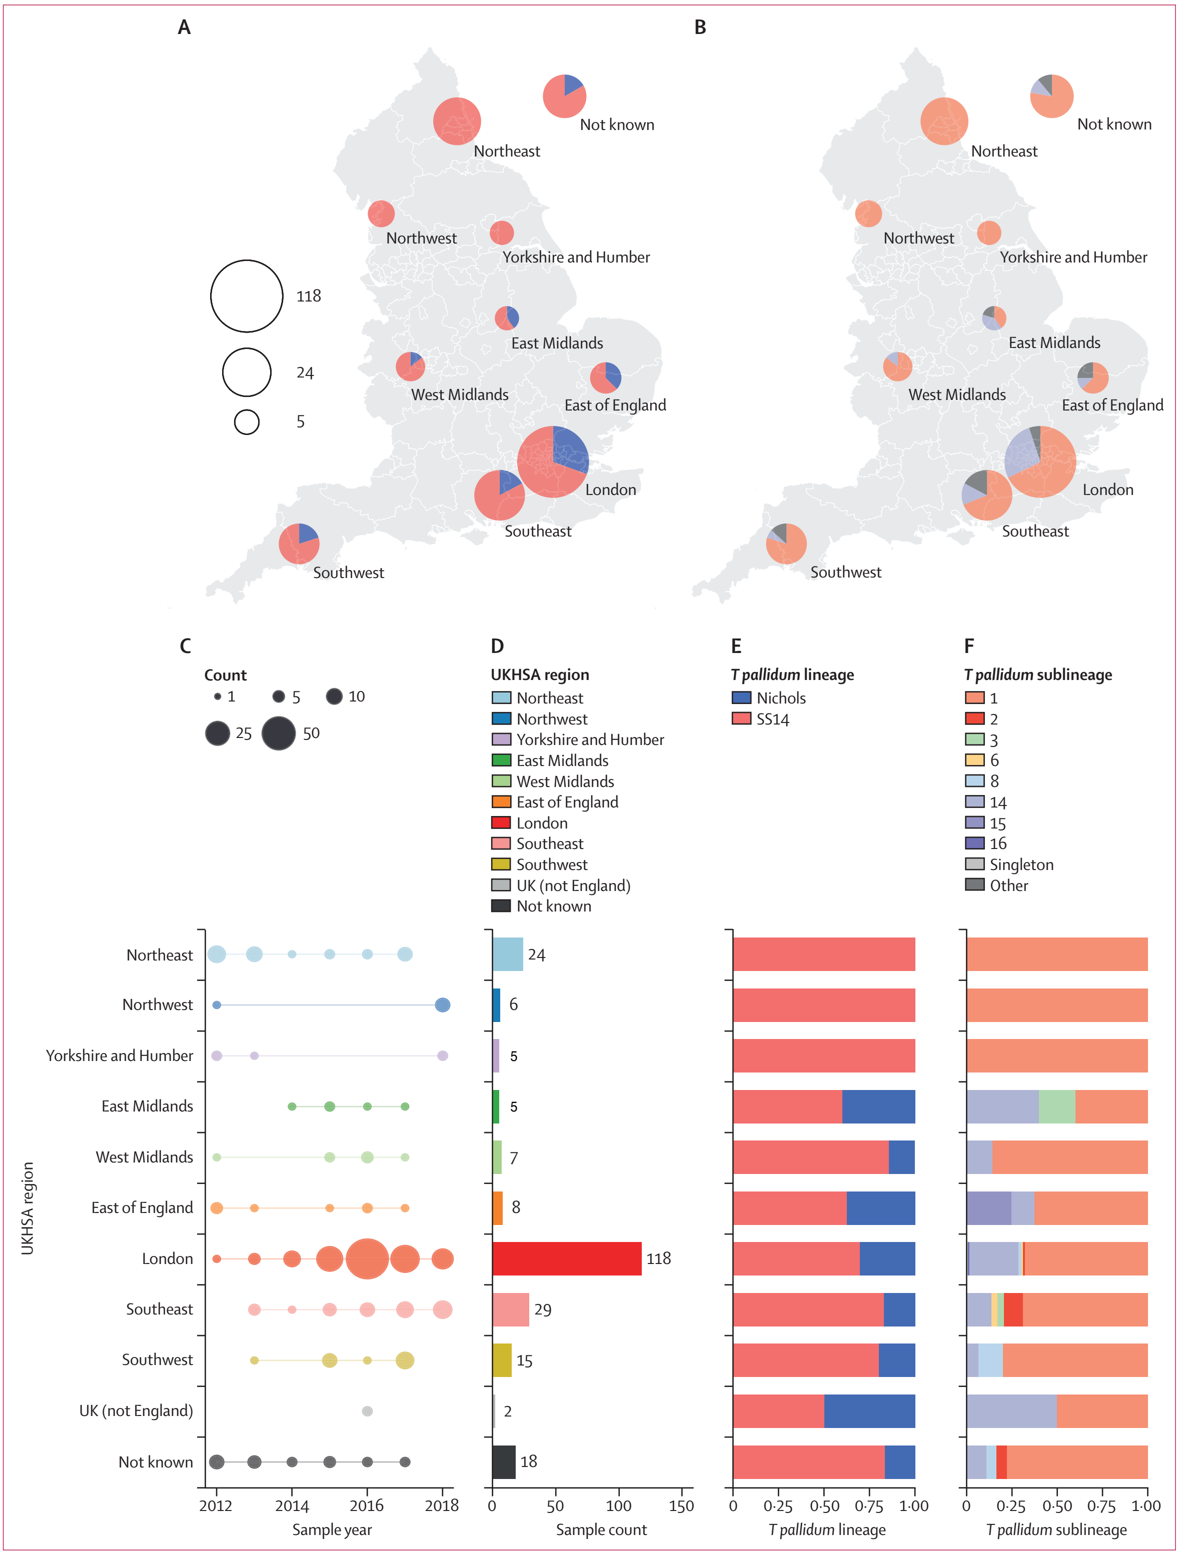

***Figure 2:* Geographical distribution of English genome samples and according to phylogenetic sublineages**
(A) Proportion of samples from each UKHSA region of England by *Treponema pallidum* subspecies *pallidum* lineage. (B) Proportion of samples in each public health region of England for the two most *common T pallidum* sublineages. (C) Distribution of sample collection years. (D) Total sample counts. (E) Proportion of samples from each region by lineage. (F) Proportion of samples from each region by sublineage. UKHSA=UK Health Security Agency.

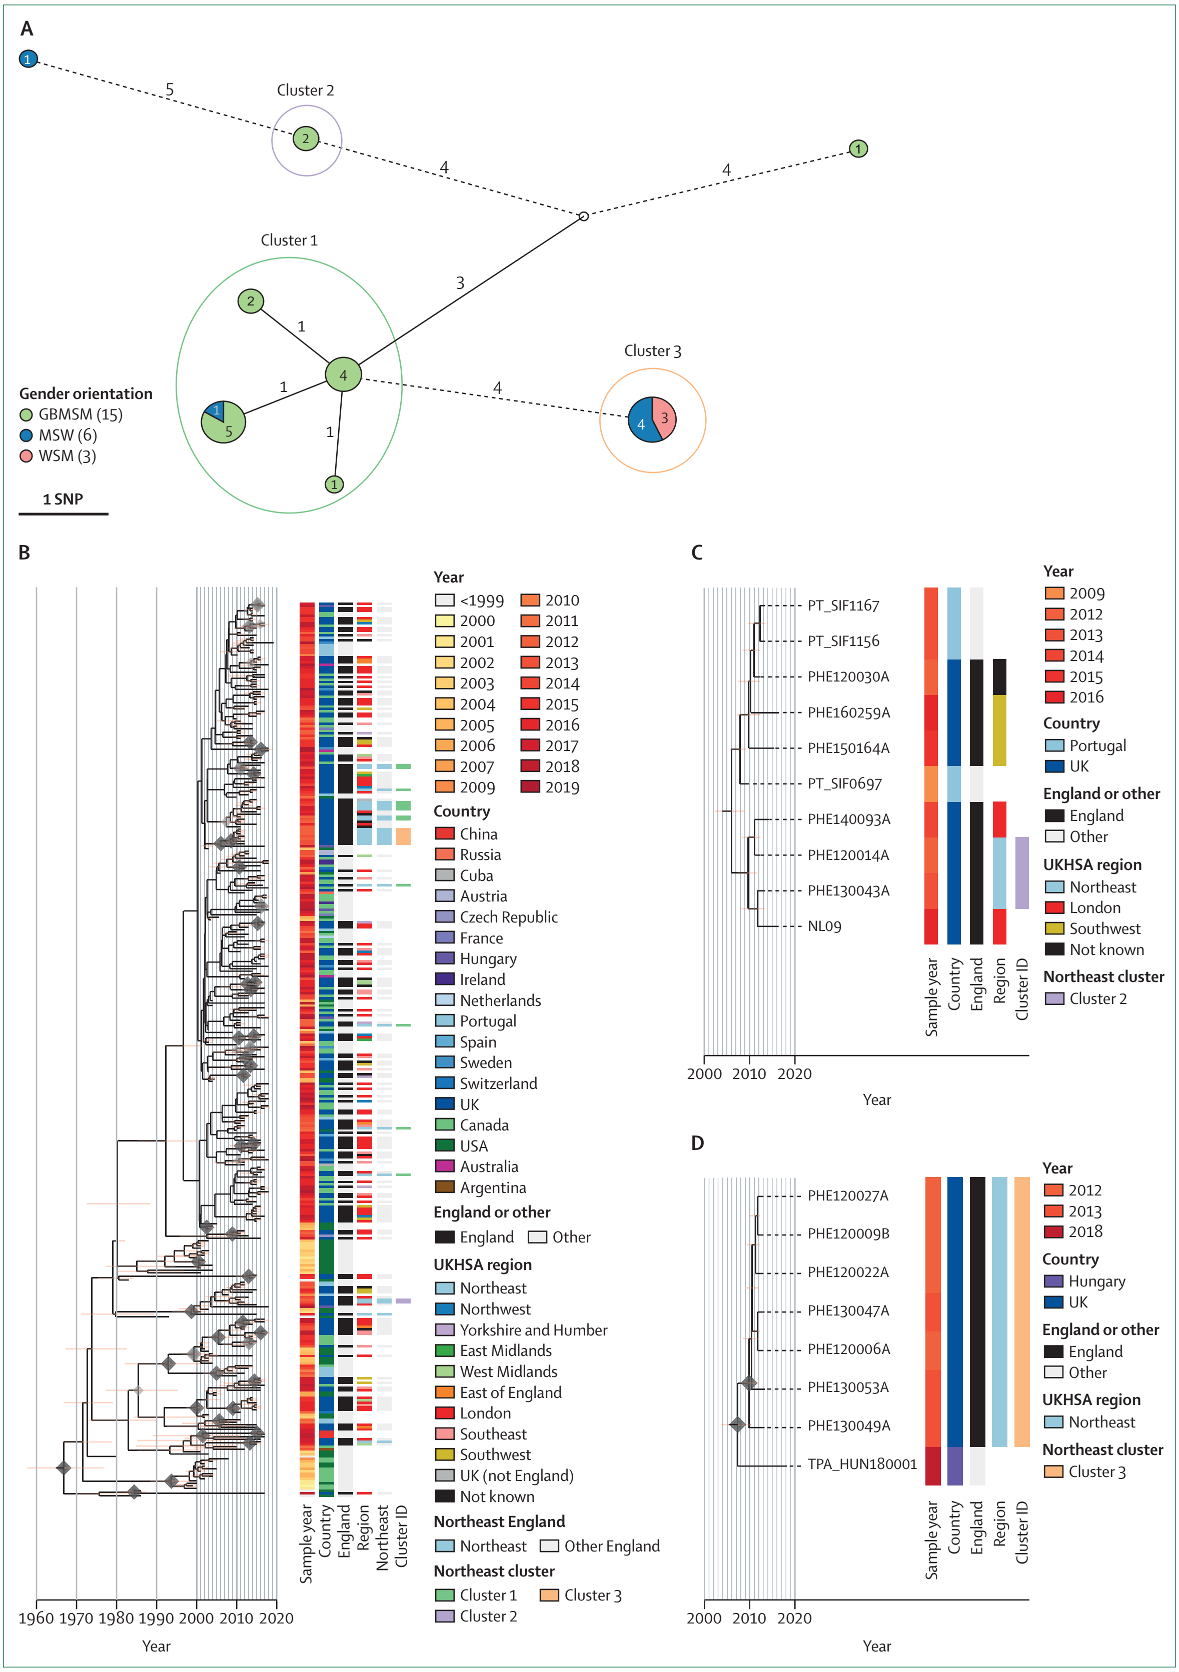

Figure 3: **Spatiotemporal and genomic clustering analysis of samples from northeast England**

(A) Minimum spanning tree visualisation of genomic relationships between samples in northeast England. Node size corresponds to the number of identical samples, and edge length (with number) to the number of substitutions between clusters (where edges were longer than 3 substitutions, these have been shortened, indicated by dashed lines). Nodes are coloured by proportion of patient gender orientation). Clusters were defined by connections to another sample within two pairwise-single nucleotide polymorphisms. Clusters 1 and 2 appear to be dominated by GBMSM populations, while Cluster 3 contains only patients identifying as heterosexual. (B) Time-scaled sublineage 1 tree of global samples indicates that the GBMSM-associated cluster 1 is a globally distributed cluster, and that the northeast samples are polyphyletic. (C) Time-scaled subtree of global samples sharing a common ancestor with cluster 2 indicates a close relationship with two samples from London, and more distantly with those from southwest England and Portugal. (D) Time-scaled subtree of global samples sharing a common ancestor with the heterosexual-associated cluster 3 suggests the northeast England samples are closely related to each other, but not to any others, with the closest related strain found in Hungary. This could imply a historic importation from another country, followed by local circulation. MSW=men who have sex with women. GBMSM=gay, bisexual and other men who have sex with men. WSM=women who have sex with men. UKHSA=UK Health Security Agency.

London, and we detected six sublineages (1, 2, 6, 8, 14, and 16) and one sublineage previously labelled as a singleton. As elsewhere, London was dominated by sublineages 1 (n=80, 67·8%) and sublineage 14 (n=32, 27·1%). The rare sublineages 15 (n=2) and 16 (n=1) were each found in a single region (sublineage 15 in the east of England and sublineage 16 in London), but all other sublineages were found in multiple regions (figure 2).

Our geospatial analysis showed that all samples from the three most northerly regions of England were from SS14 sublineage 1 (figure 2), contrasting with greater diversity elsewhere in England. To explore this in more detail, we focused on the 24 samples collected from the northeast of England between 2012 and 2017. Although all samples belonged to sublineage 1, grouping northeast samples using a two pairwise-SNP threshold identified three distinct northeast clusters within sublineage 1 (figure 3A), and correlation with the global phylogeny (figure 3B; appendix 1 p 16) indicated different distributions (figure 3B). Cluster 1 comprised samples from 13 people that were collected between 2012 and 2017, 12 of which were samples from GBMSM. Within this cluster, samples could be further subdivided into three subgroups of eleven samples linked by identical core genomes (zero pairwise SNPs; figure 3A). Phylogenetic analysis of all English and global samples from sublineage 1 showed that, although posterior support for internal nodes was low, the northeast samples appeared to be polyphyletic (figure 3B) and interspersed with samples (including additional identical genomes) from the rest of England and around the world. Therefore, it is unlikely that the northeast samples from cluster 1 represent a direct chain of transmission or local outbreak, but rather that we have sampled from a broader transmission network spanning national and global boundaries.

Cluster 2 comprised two samples collected in 2012 and 2013 from GBMSM with identical core genomes and, similarly to cluster 1, formed a clade with eight other samples, of which five were from elsewhere in England (four of five GBMSM and one of five unknown) and three were from Portugal[25] (figure 3C). By contrast, cluster 3 comprised seven samples, all of which came from the northeast in 2012 and 2013, and had identical core genomes (zero pairwise-SNPs). These samples formed a monophyletic clade, with the nearest related other sample in the global dataset separated by two SNPs and isolated from a bisexual man in Hungary in 2018 (figure 3D).[17] All seven cluster 3 patients self-identified as heterosexual (MSW or WSM). Given the close spatiotemporal and genomic relationships between cluster 3 samples, and contextualised by a background of greater diversity over the 2012–17 timespan of all other samples collected from northeast England, cluster 3 probably represents a localised outbreak in a heterosexual network. This observation, made solely on the basis of the available genomic and sociodemographic data, is consistent with reports of a syphilis outbreak in heterosexual people in the northeast.[26] It is likely that some of our samples are derived from this event.

Discussion

In this study, we linked patient demographic, spatiotemporal, and behavioural metadata to previously generated *T pallidum* genomes from 237 patients diagnosed with syphilis in England between 2012 and 2018. Our analysis shows a variety of English sublineages, dominated by global sublineages 1 and 14,[17] both of which are predicted to be resistant to macrolides, consistent with the high percentage of macrolide resistant samples in the UK. The English sublineages 1 and 14 displayed different patient sociodemographic and spatiotemporal profiles, with sublineage 1 patients showing a greater diversity of gender, sexual orientation, HIV status, and age, while sublineage 14 was primarily found in older GBMSM. Moreover, although sublineage 1 was found in all regions of England, cases attributed to sublineage 14 were mainly taken in London, and not found in the northern regions of England. These contrasting characteristics suggest that the two sublineages describe distinct sexual transmission networks, consistent with a recent WGS study from Australia,[21] which identified broadly similar *T pallidum* population structures co-circulating in Melbourne and the Northern Territory. Both common sublineages (1 and 14) contained people living with and without HIV, and there was no phylogenetic delineation by HIV status, suggesting either that HIV status might not be strongly associated with transmission patterns, or that such patterns are beyond the ability of WGS-based analyses to detect.

We were also able to examine whether the data could be used to define GBMSM and heterosexual transmission networks based on the proportion of individuals identified as GBMSM or heterosexual for each genomic cluster.[21] We observed three instances in which genomes from heterosexual individuals clustered with identical genomes only from other heterosexual people from the same region, consistent with this representing discrete heterosexual transmission networks or clusters. By contrast, we found that many genetic clusters classified as GBMSM-associated under a proportional definition across the whole dataset exhibited spatiotemporal diversity. These differences in spatiotemporal diversity could reflect differences in partner seeking behaviour and partner concurrency between GBMSM and heterosexual people.[27] We also found mixed clusters, in particular a large cluster of 42 samples with identical core genomes, most of which were from GBMSM, four from heterosexual people (one woman, three men) and three with unreported sexual orientation or gender. Samples in this cluster had diverse regional geography and spanned across the 7 years of this study, and this implies widespread dissemination through the population more rapidly than the bacteria acquires variation, and potentially represents multiple local transmission networks all sharing a recent common ancestor. The presence of heterosexual people within these networks indicates possible bridging between transmission network groups.[28]

As in most countries, samples from England were dominated by sublineage 1.[17,21] Although most English sublineage 1 patients were GBMSM, with *T pallidum* genomes occupying positions across the sublineage 1 phylogeny and interspersed with samples from around the world, in the northeast of England we identified a genetically distinct cluster of identical core genomes found exclusively in heterosexual people, consistent with reports of a syphilis outbreak in heterosexual people at that time.[26] Given the previous uncertainty as to whether genomics can have a substantial role in understanding the epidemiology of syphilis due to the genetic homogeneity and low molecular clock rate of *T pallidum*,[17,20,21] our identification of discrete clusters associated with sexual behaviour suggests WGS combined with detailed epidemiological data can resolve some local transmission chains for *T pallidum*. This could offer opportunities to intervene or educate sexual networks, and to determine or exclude outbreak membership.

In other STIs, such as gonorrhoea, SNP cutoffs of either five or ten SNPs have been used to infer transmission chains.[28,29] *Neisseria gonorrhoeae* accumulates SNPs at a rate of eight substitutions per genome per year,[30] nearly 60 times faster than *T pallidum*. Therefore, even *T pallidum* isolates with identical genomes do not necessarily indicate recent direct patient-to-patient transmission. Conversely, samples separated by even a very small number of SNPs are unlikely to share a recent common ancestor. Furthermore, because the potential transmission window of *T pallidum* might be as high as 2 years,[31,32] direct transmission cannot be excluded temporally for identical genomes collected within that period. This could ultimately limit our overall ability to deconvolute national or regional patterns of transmission.

See **Online** for appendix 2
See **Online** for appendix 3

Our study has several limitations, including the small number of samples compared to the total number of syphilis cases during the time period, and overrepresentation of samples from GBMSM in the national genome collection. The genomes represented 0·5% of the recorded number of syphilis cases in England during the study period and all samples referred to the National Reference Laboratory with sufficient treponemal DNA for sequencing. Although the available referral population might not be fully representative of syphilis in England due to regional variation in molecular testing and referral practices, all samples were collected and sequenced in the absence of any genetic relatedness information, so our genomic observations provide a snapshot of circulating English lineages. Future studies that focus on the systematic collection of samples from a higher proportion of cases, combined with improved sequence quality, will enable further insights into *T pallidum* transmission dynamics, and enable the fuller usefulness of sequence data to inform public health interventions.

Contributors

MAB, MJC, GH, MM, HF, and NRT conceptualised the study. MAB and LT contributed to methodology. MAB, LT, and HC did the formal analysis. MAB, LT, MJC, RP, and HC did the investigation. MJC, RP, ME, PF, MG, EEP, ES, JHV, KS, GH, MM, and HF provided resources. MAB, LT, HC, and KS did data curation. MAB wrote the original draft. MAB, LT, MJC, RP, HC, KS, GH, MM, HF, and NRT reviewed and edited the manuscript. MAB did the visualisation. MJC, KS, HF, and NRT supervised the trial. MAB, MJC, and MM did the project administration. KS, MM, HF, and NRT acquired funding. LT and HC accessed and verified the UKHSA data and MAB verified the underlying genomic data, the details of which have previously been reported. All authors had full access to all the data in the study (except for the detailed national patient metadata, which was restricted to UKHSA staff for patient confidentiality reasons) and accept responsibility to submit for publication. The corresponding authors had full access to all the data in the study (except for the detailed national patient metadata, which was restricted to UKHSA staff for patient confidentiality reasons), and had final responsibility for the decision to submit for publication.

Data sharing

Sequencing reads for all genomes used in this study have been previously published and described, and are available at the European Nucleotide Archive (https://www.ebi.ac.uk/ena) in BioProjects PRJEB28546, PRJEB33181, and PRJNA701499. All accessions, corresponding sample identifiers, and related metadata are available in appendix 2. Patient metadata for the UK genomes is available in pseudonymised form in appendix 3. UK shape files for Public Health region boundaries were downloaded from the UK Office for National Statistics, available at https://geoportal.statistics.gov.uk. The R code for all phylogenetic and statistical analysis and plotting is available in an Rnotebook along with all sample metadata (pseudonymised) and intermediate analysis files at https://doi.org/10.6084/m9.figshare.21543333.v1 and https://github.com/matbeale/Syphilis_Genomic_Epi_England_2022-23.

Acknowledgments

This research was funded in whole, or in part, by the Wellcome Trust (206194 and 220540/Z/20/A). MAB and NRT were supported by Wellcome funding to the Sanger Institute (206194 and 220540/Z/20/A). MM was funded by UK Research and Innovation and National Institute for Health and Care Research (COV0335; MR/V027956/1, NIHR200125) and the European and Developing Countries Clinical Trial Partnership (RIA2018D-249). Staff time for LT, MJC, RP, HC, KS, and HF and patient metadata retrieval and analyses were funded internally by UKHSA. We thank the sequencing team at the Wellcome Sanger Institute, and C Puethe and the Pathogen Informatics team for computational support, and additional technical staff involved in sample diagnostics, DNA extraction, and sample retrieval in laboratories at Public Health England (now UKHSA) and NHS laboratories (Birmingham, Brighton, Manchester, Leeds, and London), UK.

Previous studies in hepatitis B virus (HBV)-infected humans and chimpanzees suggest that control of HBV infection involves the cells, effector functions, and molecular mediators of the immune response. The objective of the current study was to identify, in the liver of acutely HBV-infected chimpanzees, the spectrum of virus-induced and immune response-related genes that regulate the infection. The results demonstrate that HBV does not induce any genes during entry and expansion, suggesting it is a stealth virus early in the infection. In contrast, a large number of T cell-derived IFN-γ-regulated genes are induced in the liver during viral clearance, reflecting the impact of an adaptive T cell response that inhibits viral replication and kills infected cells, thereby terminating the infection.

The hepatitis B virus (HBV) is a noncytopathic hepatotropic DNA virus that causes acute chronic hepatitis and hepatocellular carcinoma (1). Viral clearance and disease pathogenesis during HBV infection are tightly associated with the appearance of a vigorous T cell response to all viral proteins (2, 3). In contrast, viral persistence and chronic hepatitis are associated with a markedly diminished HBV-specific T cell response (4, 5). CD8$^+$ T cells are the main immune effector cells during HBV infection, because viral clearance and liver disease are blocked by depletion of CD8$^+$ T cells in acutely infected chimpanzees (6). Furthermore, the onset of viral clearance in these animals is tightly associated with the appearance of virus-specific T cells (6) as well as CD3, CD8, and IFN-γ mRNA (6, 7) in the liver, indicating again that the adaptive T cell response plays a key role in this process.

Although cytolytic T cell functions certainly contribute to viral clearance, noncytolytic T cell functions also play a role, because adoptively transferred HBV-specific CD8$^+$ T cells inhibit viral replication in HBV transgenic mice by a noncytopathic IFN-γ-mediated mechanism (8), and because HBV DNA largely disappears from the liver and blood long before the peak of liver disease in acutely HBV-infected chimpanzees (6, 7). Furthermore, IFN-α/β-mediated mechanisms also inhibit HBV replication noncytopathically in transgenic mice (9), and they do so by inhibiting viral capsid assembly (ref. 10 and S.W. and F.V.C., unpublished observations). Interestingly, genomic analysis of the livers and hepatocyte cell lines from those mice demonstrated a close association between the antiviral effects of both IFN-γ and IFN-α/β and the induction of hepatocellular genes that might mediate the antiviral effects (11). These genes include GTP-binding proteins (e.g., GBP-1 and TGTP) known to inhibit other viral infections (12, 13), as well as components of the immunoproteasome (LMP2, LMP7, and MECL-1), IFN-stimulated protein 15 (ISG15), ubiquitin-specific protease 18 (Usp18), the chemokine IP-10, and the signal transducer and activator of transcription (STAT)-1 (11).

The current study was prompted by the desire to validate these findings in the setting of an acute HBV infection where the genomic changes occurring during viral entry, spread, and clearance can be uniquely identified. We did so by serially profiling the liver transcriptome in three acutely HBV-infected chimpanzees, searching especially for two distinct groups of cellular genes: those whose expression might correlate with the entry and expansion of the virus that might reflect the innate immune response, and those whose expression correlates with viral clearance reflecting the adaptive immune response that terminates infection.

Materials and Methods

Chimpanzees. Three healthy young adult HBV-seronegative chimpanzees (Ch1615, -1627, and -5835) were used in this study. The animals were handled according to humane use and care guidelines specified by the Animal Research Committees at the National Institutes of Health and The Scripps Research Institute. They were housed at Bioqual Laboratories (Rockville, MD), an American Association for Accreditation of Laboratory Animal Care International-accredited institution under contract to the National Institute of Allergy and Infectious Diseases. The animals were inoculated with 10^8 genome equivalents of a monoclonal HBV isolate (genotype *ayw*) contained in pooled serum from HBV transgenic mice (14). Before inoculation and weekly thereafter, blood was obtained by venipuncture and analyzed for serum alanine aminotransferase activity (sALT) as described (8). Six weeks after inoculation, Ch1615 and -1627 received three daily i.v. injections of either a humanized chimeric monoclonal anti-human CD4$^+$ antibody (cM-T412) or an irrelevant control antibody, respectively, as described (6). The course of infection, inflammatory infiltrate, and kinetics of viral clearance were not affected in these animals (6). Liver biopsy and DNA and RNA preparation protocols are available in *Supporting Materials and Methods*, which is published as supporting information on the PNAS web site.

Gene Expression Analysis. At selected time points, 100 ng of total liver RNA isolated from frozen liver biopsies was used to prepare cRNA by the reduced-volume RNA amplification protocol described by Baugh *et al.* (15). The cRNA was hybridized to high-density oligonucleotide arrays (HG-U133A Human GeneChips, Affymetrix, Santa Clara, CA), which interrogate the expression of ≈22,000 human genes. Primary image analysis was performed with GENECHIP VERSION 5.0 (Affymetrix). Relative gene expression levels were normalized throughout the entire data set by using algorithms in the DCHIP software package (16, 17). Genes not called "present" by GENECHIP at least at one time point were excluded from further analysis, and the remaining values were logarithm-transformed to base 10. Genes were identified whose expression correlated (by Pearson's correlation) either with the pattern of log-transformed intrahepatic HBV DNA or with the expression profile of specific prototype cellular genes described in the text. A Pearson correlation coefficient of ≥0.7 over all time points in all three chimpanzees was required for a gene to be further analyzed. Finally, selected genes had to be called "present" at the peak of intrahepatic HBV DNA levels or at the expression maxima of specific prototype genes, and they had to be called "induced" by GENECHIP at the same time point

relative to the preinfection sample in all three animals. Genes were selected as "induced during viral clearance" if they were called "present" and "induced" relative to preinfection levels in weeks 12, 14, and 16 in Ch1627, 14 and 16 in Ch1615, and 14 and 18 in Ch5835. In addition, the expression level of these genes had to be higher during viral clearance than during the weeks before peak viremia in the same animal (i.e., weeks 4 and 6 in Ch1627 and 2 and 4 in Ch1615 and -5835). For Ch1627, HBV clearance-associated genes were grouped according to their induction kinetics into early, middle, and late genes based on the week (i.e., 12, 14, or 16) when peak induction was observed. Gene expression profiles were visualized by using GENESPRING VERSION 5.0 (Silicon Genetics, Redwood City, CA) by using gene expression values normalized to the 10th and 90th percentiles for each gene.

Results

Course of HBV Infection in Acutely Infected Chimpanzees. Ch1615, -1627, and -5835 were inoculated i.v. with 0.5 ml of HBV-transgenic mouse serum containing 1×10^8 genome equivalents of HBV DNA (6). As shown in Fig. 1, all three animals, including the CD4-depleted animal, became infected, developed acute hepatitis, and cleared the infection with remarkably similar kinetics (liver HBV DNA levels are shown in Table 2, which is published as supporting information on the PNAS web site). Viral spread in Ch1627 (Fig. 1*A*) and -5835 (Fig. 1*C*) was not accompanied by induction of CD3, IFN-γ, or 2′5′ oligoadenylate synthetase (2′5′OAS) mRNA, which was monitored by RNase protection analysis (Fig. 1), suggesting that the virus was not recognized by the innate or adaptive immune response in those animals at that time. In contrast, CD3, IFN-γ, and 2′5′OAS mRNA were all transiently induced in Ch1615 during week 5, coinciding with a transient spike of elevated sALT activity (Fig. 1*B*). All of these events were abruptly terminated by antibody-mediated CD4 depletion during week 6 (Fig. 1*B*, vertical arrow), suggesting that they reflected the atypically early onset of an adaptive immune response in this animal. This notion is further supported by the observation that, several weeks later, viral clearance in all animals coincided with the appearance of CD3, IFN-γ, and 2′5′OAS mRNA (Fig. 1), elevated sALT (Fig. 1), and HBV-specific T cells in the liver (ref. 6 and data not shown). Collectively, these results suggest that these T cells and their products contributed to viral clearance in these animals. Importantly, in all three animals, the viral DNA decreased 10- to 50-fold in the liver before the number of hepatitis B core antigen-positive hepatocytes began to decrease (Fig. 1), indicating that the decrease in viral DNA did not reflect the destruction of infected cells.

Liver Gene Expression Profiles in Acutely Infected Chimpanzees. The stars in Fig. 1 indicate the time points when liver gene expression profiling was performed in the animals. In this study, we attempted to identify two classes of genes: one group whose expression correlated with hepatic viral DNA content and therefore could reflect the initial (innate) host response to HBV in the liver, and a second group whose expression correlated with viral clearance and who are likely to be induced by the adaptive immune response to the virus.

Liver Genes Induced by HBV. The first group of genes displayed expression patterns that correlated (directly or inversely) with the amount of HBV DNA in the liver over the entire time course profiled. To reduce the chance of misinterpreting random fluctuations in gene expression in individual animals, we calculated the Pearson correlation between the expression of each gene and the amount of HBV DNA at each time point in all three animals, and we restricted our focus to genes whose changing expression levels correlated with the changing viral DNA content in the liver with a correlation coefficient of at least 0.7. Importantly, as shown in Fig. 2*A*, no genes fulfilled these criteria. Furthermore, no transcripts were uniformly induced or repressed if we limited our focus solely

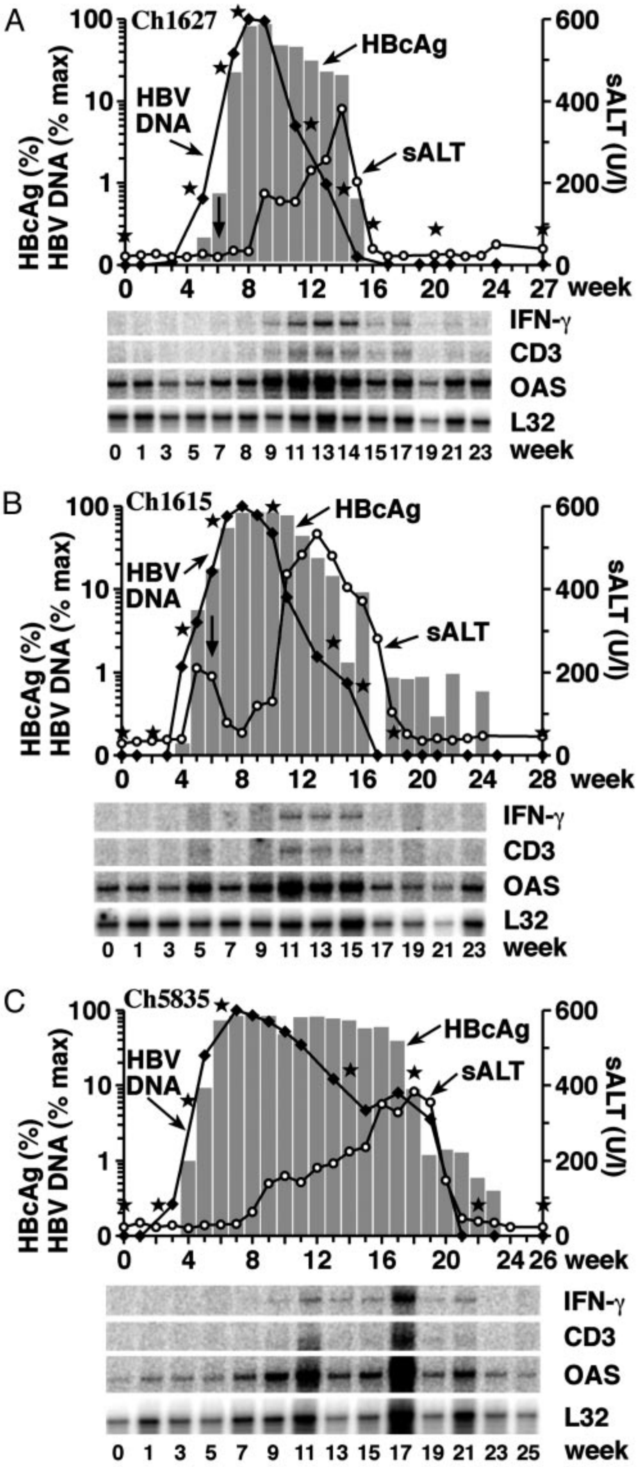

Fig. 1. Course of acute HBV infection in chimpanzees after experimental i.v. inoculation of 10^8 genome equivalents of HBV in week 0. (*A*) Ch1627 was also injected with an irrelevant control antibody in week 6. (*B*) Ch1615 was injected with a CD4-specific monoclonal antibody as described in the text. (*C*) Ch5835 did not receive any additional treatment. Intrahepatic HBV DNA (black squares) is expressed as a percentage (% max) of the peak HBV DNA levels in the liver of each animal (actual liver HBV DNA levels are presented in Table 2). Hepatitis B core antigen-positive (HbcAg) hepatocytes (gray bars) are expressed as percentage of the total number of hepatocytes. sALT (open circles) is expressed in units per liter. Intrahepatic expression profiles for IFN-γ, CD3, and 2′5′OAS were determined by RNase protection assay. Vertical arrows indicate the time of antibody injection. Stars indicate the time points for which gene expression profiling was performed.

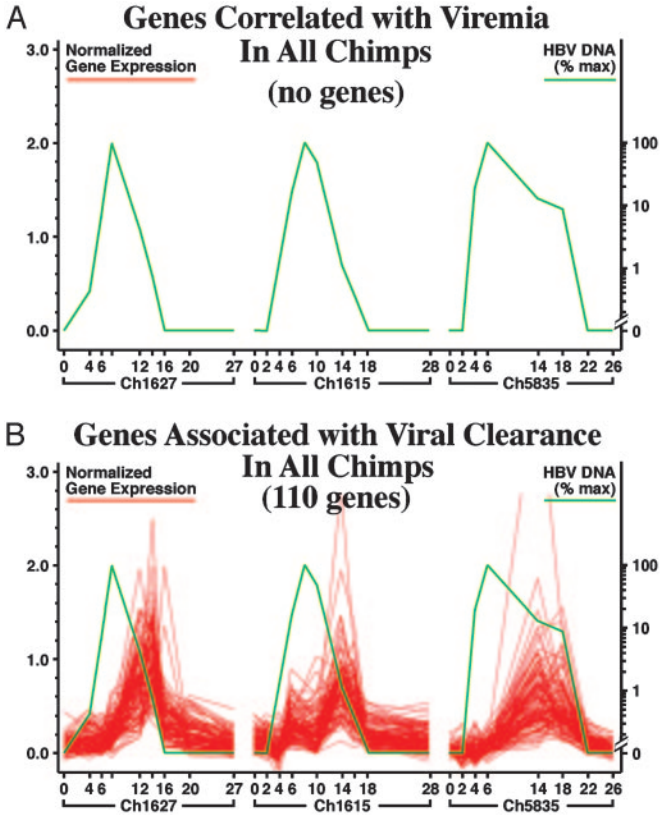

Fig. 2. Liver gene expression profile during acute HBV infection. (*A*) Genes correlated with viremia in all chimpanzees. No genes correlated positively or negatively with the level of intrahepatic HBV DNA during the time course of acute HBV infection in all three animals. (*B*) Liver gene expression profile associated with viral clearance in all three acutely HBV-infected chimpanzees. The gene identities are shown in Table 1 and the primary data in Tables 3 and 4. Green lines show the intrahepatic HBV DNA as a percentage (% max) of the corresponding peak levels. For optimal visualization, gene expression levels (red lines) are shown after normalization to the 10th and 90th percentiles for each gene. Values on the *x* axis represent weeks after inoculation with HBV.

to the lag phase of infection (weeks 0–2 in Ch1615 and -5835) or to the phase of logarithmic expansion (weeks 4–6 in Ch1615 and -5835 and weeks 4–7.5 in Ch1627) of the virus (data not shown). Because virtually 100% of the hepatocytes were infected in all three animals (see hepatitis B core antigen-positive hepatocytes in Fig. 1), the failure of the virus to induce cellular gene expression as it spread throughout the liver suggests that HBV does not induce an innate immune response at the site of infection.

Liver Genes Associated with Viral Clearance. To identify genes associated with viral clearance, we searched for transcripts that were either induced or suppressed when viral DNA disappeared from the liver. We identified 59 unique genes ("Selected as induced during viral clearance," Table 1, and indicated with a Y in column 5 of Table 3, which is published as supporting information on the PNAS web site) that were induced during viral clearance in all three animals (average peak fold change, 10.7), and none that were suppressed. The expression profile of these genes reflects a type 1 T cell response, because it was heavily weighted toward genes expressed by α/β T cells (e.g., T cell receptor β), γ/δ T cells (e.g., T cell receptor γ), the cytolytic effector molecule granzyme A, and many genes known to be induced by IFN-γ, which itself correlated with viral clearance (Fig. 1). The IFN-γ-induced genes include *STAT1*, MHC class I, MHC class II, immunoproteasome subunits *LMP2*, *PA28α* and -*β*, ubiquitin D, *E2L6*, tapasin, the chemokines monokine induced by IFN-γ (*MIG*), *IP-10*, and *RANTES*, the GTPase *GBP2*, and several other IFN-γ-induced genes [e.g., *IFI27* (18) and *IFI30* (19), and tryptophanyl-tRNA synthetase (20)], whose relevance to the T cell response and viral clearance is not immediately apparent. IFN-γ itself, however, is not in this list because it was scored present in only a few samples (data not shown and Table 4, which is published as supporting information on the PNAS web site), suggesting that the absolute level of intrahepatic IFN-γ expression (Fig. 1) was too low to be consistently detected by the microarrays used. 2′5′OAS, which is induced during viral clearance (Fig. 1), also is not part of this list, because its induction during viral clearance in Ch1615 was very brief (Table 4) and therefore did not satisfy our selection criteria. In addition, several genes not known to be inducible by IFN-γ (e.g., apolipoprotein L3, butyrophilin A3, cathepsin C, cofilin 1, complement component C1q, galectin 3, lysozyme, *Plac8*, superoxide dismutase, and Ig heavy and light chain alleles) were also induced during viral clearance.

Next, to identify viral clearance-associated genes that might have been excluded by our stringent selection criteria, we searched for genes whose expression correlated with the profiles of prototype genes, specifically T cell antigen receptor (*TCR*)*β*, *TCRγ*, *CD3D*, *IFN-γ*, *MIG*, *RANTES*, *IP-10*, and sALT, as indicated in columns 6–13 of Table 3. This increased the number of genes induced during viral clearance to 110, all of which are shown in Fig. 2*B* and identified in Tables 1 and 3.

This list contains additional T cell (*CD38*, *CD53*, and granzyme A), natural killer (NK) cell (*CD53* and granzyme K), B cell (*CD48* and *CD83*), macrophage (*CD68*), chemokine (*CXCL11* and *CXCR4*), GTPase (*GBP1*), complement (*C3a*), IFN-stimulated (*ISG20* and *IFI16*), and immunoproteasome (*MECL-1*) genes that were not included in the first-pass analysis. Importantly, 84 of these 110 genes were closely correlated with the TCRβ and -γ mRNA expression profiles (Table 3), 88 correlated with the induction profiles of *MIG*, *IP-10*, or *RANTES*, which are known to be highly induced by IFN-γ (21, 22), and 79 correlated with sALT levels in all three chimpanzees (Table 3 and Fig. 1). It is noteworthy that all of these genes returned to baseline when the viral DNA was eliminated (Fig. 2*B*). Because that correlation was not required for a gene to be designated as "clearance-associated," it strongly supports the notion that these genes were functionally related to viral clearance.

Sequential Induction of Clearance-Associated Liver Genes in Ch1627. Examination of the clearance-associated gene expression profile of Ch1627 (Figs. 2*B* and 3) reveals three distinct gene clusters whose expression peaked in week 12, 14, or 16 and were designated early, middle, and late clearance genes, accordingly (Fig. 3). The spacing of the sampled time points in the other chimpanzees did not permit sequential gene clusters to be identified in those animals. As shown in Table 1 and Fig. 3 (in blue), the early gene cluster consisted of 35 genes that included the TCRβ locus, several IFN-γ-induced genes including MHC class I and II genes, the TAP-binding protein (tapasin), the immunoproteasome components PA28α and -β, the chemokine *RANTES*, and IFN-γ-inducible protein 30, suggesting that they are mainly T cell-related and IFN-γ-induced genes that mediate antigen processing and presentation and inflammatory cell recruitment.

The middle gene cluster [Fig. 3 (shown in red) and Table 1] consisted of 73 genes, including *CD3D*, the TCRγ locus, a T cell activation marker (*CD38*), and the cytolytic effector granzymes A and K, as well as a T-LAK cell-originated protein kinase, a macrophage antigen (*CD68*), and a B cell membrane protein (*CD48*). Several additional IFN-γ-induced genes were also detected, including *STAT1*, the chemokines *IP-9*, *IP-10*, and *MIG*, the immunoproteasome component *MECL-1*, several ubiquitin-related genes, the GTPase *GBP1*, and its closely related family member GTPase guanylate-binding protein 2. Thus, the second wave of

Table includes genes selected as induced during viral clearance (+) and/or correlated with prototype marker genes as described in the text. chimps, chimpanzees; HCs, hepatocytes; HBVtg, HBV transgenic; reduc., reductase; prot., protein.

*Peak expression early (E), middle (M), or late (L) during viral clearance in Ch1627.

[†] Induced during clearance in hepatitis C virus (HCV)-infected chimpanzees (23).

[‡] Induced by IFNβ and/or IFNγ in murine hepatocytes during clearance of HBV (11).

genes expressed during viral clearance in this animal reflects the amplification and diversification of the intrahepatic inflammatory response and the induction of antiviral activity within the infected cells.

Only two of the clearance-associated genes (i.e., Ig heavy and light chains) reached peak induction late in infection in this animal [Fig. 3 (shown in green) and Table 1], reflecting the expansion of a B cell infiltrate when the viral DNA was disappearing from the liver.

Discussion

The objective of this study was to identify liver genes that are transcriptionally regulated during HBV infection and are associated with either the entry and expansion of the virus or its immune-mediated clearance. The first group could include proviral genes that the virus might induce to optimize replication and antiviral genes that reflect the activation and/or effector functions of the innate immune response. The second group should include genes brought into the liver by cells of the adaptive immune response, plus

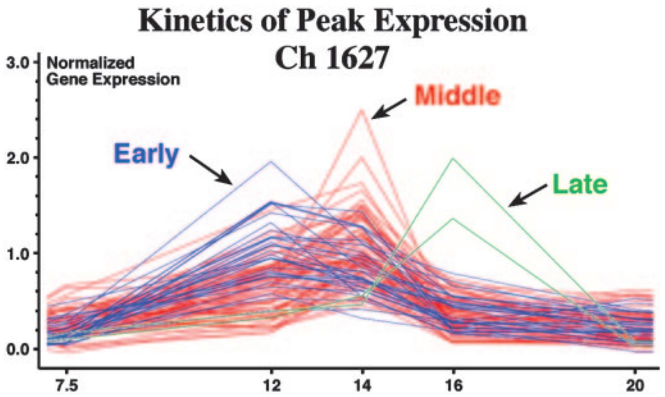

Fig. 3. Kinetics of liver gene expression during viral clearance in Ch1627. Early (blue), Middle (red), and Late (green) genes displayed maximal expression in weeks 12, 14, and 16, respectively.

hepatocellular genes that are activated by those cells and their products, e.g., IFN-γ.

These studies were modeled after a previous report from our laboratory (23) in which the genes associated with HCV spread and clearance were identified in the livers of chimpanzees that were acutely and chronically infected by HCV. Together, the results of the two studies display remarkable differences in the repertoire of genes that are induced during the infection by HBV in this study (no genes) and HCV in previous studies (23, 24) (27 genes, many of which are regulated by IFN-α/β), probably reflecting differences in the genome structure and the replication strategies of the two viruses and corresponding differences in their ability to induce an innate immune response. The results also reveal remarkable similarities in the repertoire of genes induced during viral clearance in both HBV and HCV infections (23, 24) and during T cell-mediated viral clearance in the HBV transgenic mouse model (11) (Table 1), probably reflecting similarities in the adaptive immune mechanisms responsible for their control. The results also illustrate that γ/δ T cells contribute to the inflammatory infiltrate during acute hepatitis B, and they identify a compact subset of candidate antiviral genes, some of which could mediate viral clearance by interrupting the HBV life cycle in infected cells.

IFN-α/β and -γ are known to inhibit viral replication in the liver of HBV transgenic mice (8–10, 25). Both cytokines are produced during the innate immune response, IFN-α/β primarily by infected cells and plasmacytoid dendritic cells (26, 27), and IFN-γ primarily by NK and NKT cells (28), which are abundant in the liver (28, 29). Thus, because we and others have shown that the expression of a large number of IFN-regulated genes is rapidly and consistently induced in the liver of HCV-infected chimpanzees and that the strength of their expression correlates with viremia (23, 24), we expected the same to occur in the HBV-infected animals. Surprisingly, not a single gene was induced or repressed by HBV in all three acutely infected animals. Furthermore, no genes were significantly up- or down-regulated in any of the animals in the lag phase of infection or the log phase of viral spread. These results imply that HBV did not induce an intrahepatic innate immune response that could be detected by gene chip analysis in all of the infected animals. The basis for this is not immediately clear. It may reflect the replication strategy of HBV whose DNA genome replicates within nucleocapsid particles (30) and thus is shielded from the cellular machinery that normally senses double-stranded RNA (31). It also implies that extracellular HBV virions and subviral products are not detected by the toll-like receptor system (32).

Many RNA viruses have developed elegant strategies to evade the antiviral effects of cytokines induced during the innate immune response (26). The need to develop these strategies exists for these viruses because they induce IFN-α/β in infected cells or IFN-γ by cells of the innate immune system. We suggest that HBV achieves the same end by not inducing these cytokines in the first place. An interesting consequence of this is that by not needing to evade IFN early in the infection, the virus remains susceptible to IFN later in the infection when the adaptive immune response begins (6, 33).

In contrast to the apparent invisibility of HBV to the innate sensing machinery, when CD3$^+$ MHC-restricted α/β receptor T cells appeared in the liver of the infected animals [Table 1 and Fig. 2*B* and 3 (shown in blue)], a temporal and functional cascade was initiated that correlated very strongly with the induction of IFN-γ and viral clearance. Because the IFN-γ-inducible chemokine MIG was induced immediately before the onset of clearance in all three animals (data not shown), it is likely that IFN-γ played a major role in inducing most of the viral clearance-associated genes detected in this study, including 2′5′OAS, which is known to be inducible by IFN-γ (34). By using Ch1627 as a prototype, the early appearance of TCRα/β receptor genes [Table 1 and Fig. 3 (shown in blue)] was accompanied by the induction of IFN-γ-regulated genes (e.g., MHC class I, MHC class II, immunoproteasome components *PA28*α and *PA28*β, and the TAP-binding protein tapasin), all of which may have facilitated antigen processing and presentation to the incoming T cells. In addition, the early induction of *RANTES*, *MIG*, and *IP-10* probably enhanced the recruitment of additional inflammatory cells into the liver. The remaining early genes underlie a wide array of cellular functions, some of which might contribute to viral clearance. For example, ISG20 is an IFN-inducible RNase that increases the resistance to infection by RNA viruses (35) and is also induced during IFN-mediated suppression of viral replication in HBV transgenic mouse hepatocyte cell lines (11). Thus, ISG20 may also be able to destroy HBV RNA in infected hepatocytes. Additional studies are needed to test this hypothesis.

The early peak was followed by a second group of genes [Table 1 and Fig. 3 (shown in red)] reflecting expansion of the inflammatory infiltrate to include γ/δ T cells. γ/δ T cells do not express CD4 or CD8, do not recognize peptide antigens, and are MHC-unrestricted (36), but they have been shown to produce IFN-γ and contribute to the clearance of other viral infections (36, 37). Thus, further investigation of γ/δ T cell immunobiology in HBV infection appears to be warranted.

The middle gene cluster [Table 1 and Fig. 3 (shown in red)] also displays further evidence of T and NK cells and macrophage activation in the liver, because *CD38* and the T cell and NK cell death effectors granzyme A and granzyme K peaked at this time, as did a large number of IFN-γ-regulated genes, consistent with the detection of IFN-γ mRNA and the decreasing viral DNA content of the liver (Fig. 1). For example, *STAT1*, which mediates IFN receptor signaling, was maximally induced at this time, as were several MHC class II genes, the chemokines *IP-10*, *MIG* and *IP-9*, the immunoproteasome components *LMP2* and *MECL-1*, ubiquitin D, and the ubiquitin-conjugating enzymes E2C and E2L6, all of which likely contribute to the inflammatory process. In addition, the IFN-γ-induced GTPases, GBP1 and -2, as well as *IFI27* and *IFI16*, peaked at this time. Interestingly, the murine homologues of *GBP1* and *IFI27* inhibit vesicular stomatitis virus (12) and Sindbis virus infection in mice (38), respectively, and they are induced in IFN-treated murine hepatocyte cell lines when HBV replication is suppressed (Table 1). Thus, further investigation of the role these genes play in viral clearance during HBV infection appears to be warranted.

Last, the middle gene cluster contains several other genes that could play a role in viral clearance and/or disease pathogenesis during HBV infection. Among these are members of the Ras-related family of small GTPases (i.e., *Rab20*, *-27a*, and *-31*) (reviewed in ref. 39) that might inhibit HBV replication by virtue of their ability to regulate vesicular transport (39–41). Cathepsin B is a cysteine protease that is released into the cytoplasm (42) during hepatocyte apoptosis where it might also target HBV. Karyopherin (importin-α) induction might also influence HBV replication because it is known to regulate HBV capsid nuclear import (43).

The last (late) wave consisted of Ig heavy and light chain genes [Table 1 and Fig. 3 (shown in green)], apparently reflecting an influx of B cells into the liver.

Although the results of this study elucidate and strongly underscore the role of the adaptive immune response and its products in viral clearance during acute HBV infection, they do not discriminate among genes that are expressed in the inflammatory cells or the hepatocytes. Although this should be clarified in future studies, some insight can be gained by comparing the current results with our previous analysis of the gene expression profiles of HBV transgenic murine hepatocyte cell lines in which HBV replication was suppressed by IFN-β and -γ *in vitro*. As shown in Table 1, a relatively compact panel of genes [*STAT1*, *IFI16*, *GBP1*, *GBP2*, *LMP2*, *MECL-1*, *PA28*α/β, *IP-10*, *MIG*, *ISG20*, leucine aminopeptidase 3, placenta-specific 8, tryptophanyl-tRNA synthetase (*TrpRS*), β-2-microglobulin, ubiquitin-conjugating enzyme *E2L6* (*UBE2L6*), tapasin, and MHC class I] was induced during viral clearance in all three chimpanzees and in IFN-β- and/or -γ-treated mouse hepatocytes (11), suggesting that they may function as effector molecules that suppress viral replication and contribute noncytolytically to the control of HBV infection. The generality and potential importance of this subset of genes are underscored by the fact that several of them are also induced in the liver during viral clearance in HCV-infected chimpanzees (23, 24).

Conclusion

The current results suggest that HBV acts like a stealth virus early in infection, remaining undetected and spreading until the onset of the adaptive immune response several weeks later. When MHC-restricted α/β T cells enter the liver and recognize antigen, they kill some of the infected cells and secrete IFN-γ, which induces the expression of a large number of genes that enhance antigen processing and presentation; recruit macrophages, NK cells, and γ/δ T cells that also produce IFN-γ; and amplify the process. Several of the IFN-γ-induced genes have antiviral activity in other systems, raising the possibility that they may also inhibit HBV replication. These highly coordinated cellular and molecular events continue until the infection is terminated, at which point they rapidly subside. Because many of the same genes are also associated with clearance of HCV, they represent a starting point for further elucidation of the cellular and molecular immunobiology of these infections.

ARTICLE

Genomic correlates of variability in immune response to an oral cholera vaccine

Partha P Majumder[*,1,2], Neeta Sarkar-Roy[1,2], Herman Staats[3], T Ramamurthy[4], Sujit Maiti[2,5], Goutam Chowdhury[4], Carol C Whisnant[6], K Narayanasamy[7,8] and Diane K Wagener[6]

Cholera is endemic to many countries. Recent major outbreaks of cholera have prompted World Health Organization to recommend oral cholera vaccination as a public-health strategy. Variation in percentage of seroconversion upon cholera vaccination has been recorded across populations. Vaccine-induced responses are influenced by host genetic differences. We have investigated association between single-nucleotide polymorphic (SNP) loci in and around 296 immunologically relevant genes and total anti-lipopolysaccharide (LPS) antibody response to a killed whole-cell vaccine, comprising LPS from multiple strains of *Vibrio cholerae*. Titers derived from standard vibriocidal assays were also analyzed to gain further insights on validated SNP associations. Vaccination was administered to 1000 individuals drawn from India. Data on two independent random subsets, each comprising ~500 vaccinees, were used for discovery of genomic associations and validation, respectively. Significant associations of four SNPs and haplotypes in three genes (*MARCO, TNFAIP3* and *CXCL12*) with AR were discovered and validated, of which two in *TNFAIP3* and *CXCL12* were also significantly associated with immunity (fourfold increase in vibriocidal titers). *CXCL12* is a neutrophil and lymphocyte chemoattractant that is upregulated in response to *V. cholerae* infection. LPS in the vaccine possibly provides signals that mimic those of the live bacterium. *TNFAIP3* promotes intestinal epithelial barrier integrity and provides tight junction protein regulation; possible requirements for adequate response to the vaccine. LPS is a potent activator of innate immune responses and a ligand of *MARCO*. Variants in this gene have been found to be associated with LPS response, but not with high vibriocidal titer level.

INTRODUCTION

Major outbreaks of cholera, leading to several thousand deaths, in Zimbabwe in 2009 and in Haiti in 2010, prompted the World Health Organization to emphasize the administration of oral cholera vaccination.[1–4] Cholera is caused by toxicogenic strains of the Gram-negative bacterium *Vibrio cholerae*. Moderate to severe watery diarrhea, that appears within 1–5 days of ingestion of contaminated food or water, rapidly leads to dehydration and, if left untreated, to death. It is a significant cause of mortality in developing countries,[5] and is still endemic in many countries, including India.[6] Unfortunately, 13% of the world's population still lacks access to safe water.[7]

V. cholerae, has two major serogroups – O1 (serotypes Inaba and Ogawa) and O139 – that are responsible for most cholera cases and differ in the lipopolysachharide (LPS) structures of the outer membrane.[8] Immunity to cholera can be acquired.[9] WHO advocates vaccination for cholera.[10] The efficacy of currently available vaccines varies across populations; protective efficacy is unlikely to last more than 3 years.[11] A single-dose cholera vaccine that induces long-term immunity for those at risk remains an unfulfilled goal.[12] Persons of blood group O are more susceptible to cholera than non-O blood group persons.[13–15] However, the association between efficacy of cholera vaccines and O blood group has been inconsistent–negative in Bangladesh,[13] positive in Indonesia[16] and no association in India.[17] Inter-individual variability in immune response to vaccines impedes the control of infectious diseases. Primary failure, as assessed by postvaccination antibody levels, of vaccines is a problem; 2–10% for measles vaccine,[18,19] 5–20% for hepatitis B vaccine[20,21] and 23–40% for typhoid vaccine.[22,23] Data are unavailable for cholera vaccines. Twin studies have shown high heritability for antibody response (AR) to measles (89%), mumps (39%), rubella (46%), hepatitis B (61–77%), oral polio (60%), tetanus (44–64%), diphtheria (49%), *Haemophilus influenzae* type B (Hib) (51%) and other vaccines.[24] Polymorphic variants in HLA and other genes–such as, *IL1B, IL4R, IL6, IL10* and *TNF*–are associated or linked with AR to several vaccines.[18,25–30] Although measles, mumps and rubella vaccines are all attenuated-live vaccines that are administered simultaneously, the responses induced by these vaccines are influenced differently by host genetics.[24] Vietnam is the only country in the world with large cholera-endemic tracts where an oral vaccine for cholera has been widely used for a long time (since 1997).[31] Considerable variation in response among vaccinees was noted in a clinical trial of this vaccine[31] conducted in a non-endemic area of Vietnam (Son La province), although >90% of vaccinees seroconverted. However, in respect of the same vaccine, only ~50% of vaccinees seroconverted in the endemic area of West Bengal, India.[17]

Received 10 July 2012; revised 23 October 2012; accepted 20 November 2012; published online 19 December 2012

Vaccine response is not wholly determined by the genetic make-up of vaccine recipients, but also by the nature of microbial antigens and adjuvants.[32] Knowledge of key immunogenetic associations can be used to design a vaccine that circumvents immunogenetic restrictions.[33] Insights into the impact of genetic variation in vaccinees on AR has been obtained for some vaccines.[24,34,35] In this study, we have investigated, for the first time, whether variation in the genomic backgrounds of vaccinees contributed to variation in immunological response to the killed whole-cell bivalent oral cholera vaccine, which has been introduced in India in 2010.

METHODS

Study participants

Individuals ($n=1000$), unrelated at least to the first-cousin level based on family history report, aged 14 years or older, inhabiting a socio-economically depressed locality of Kolkata (formerly, Calcutta), India, were recruited using a statistical sampling design,[34] with institutional ethical approval and written individual informed consent. Exclusions included: (a) pregnant and lactating women and (b) based on self-report, individuals who had ever been diagnosed with cholera or had suffered from diarrhea or vomiting during the week preceding recruitment. The sample of 948 vaccinees, whose data passed all the quality checks (explained later), was randomly split into two half-samples (HSs); one used for association-discovery and the other for association-validation.

Vaccination and collection of blood samples

With approval of the Drug Controller General of India, a two-dose vaccine (see online Supplementary Table S1 for composition) procured from Shantha Biotechnics, Hyderabad, India, orally administered 14 days apart, was used. The vaccine was stored and transported at 4–8 °C before administration. From each vaccinee, a blood sample was collected immediately before vaccination (Day 0 sample) and 28 days postvaccination (Day 28 sample).

Assessment of antibody level

Antibody level was assessed using two different methods as described below.

Total anti-LPS AR assay. Serum anti-*V. cholerae* (Inaba 569) LPS–that is, total anti-LPS antibody–was assayed using the Bio-Plex (Bio Rad, Hercules, CA, USA) platform (hereafter referred to as the 'Bioplex assay'). *V. cholerae* O1 (Inaba 569) LPS (List Biological, Cat. No.231) was conjugated to Bio Rad beads (COOH (042)) by Solulink (San Diego, CA, USA). Day 0 and Day 28 human sera were incubated with LPS beads with anti-*V. cholerae* LPS antibody and responses were detected using a cocktail of anti-human IgG-PE, IgA-PE and IgM-PE. A pooled serum with a high anti-LPS IgG/IgA/IgM response was used to create a standard curve that was assigned an arbitrary value of anti-LPS Ig ELISA units (EU)/ml. Responses (Day 0 and Day 28) in individual subjects were compared with the standard curve to calculate anti-LPS Ig EU/ml.

Vibriocidal assay. This assay was performed with *V. cholerae* O1 Inaba (OS-418), Ogawa (MAK757) and uncapsulated O139 (MO-10T4) strains using sera collected during pre- and postvaccine trials following published methods.[36] Commercially available guinea-pig serum (Rockland, Gilbertsville, PA, USA) was used as a source of complement. The sera (100 μl) were added to 100 μl of PBS in the first well to give twofold dilution and the subsequent dilutions were made reciprocally up to 4800. Reference rabbit antiserum against *V. cholerae* O1 Inaba, Ogawa and O139 were included in each set of assay as controls. In every batch of assay, sera obtained from a healthy volunteer and a high-titer antiserum obtained from one of the volunteers in this study were included as negative and positive controls, respectively.

Candidate genes and SNPs

We selected 296 autosomal genes from immunological pathways as candidates for this association study. Two thousand four hundred and eighty-eight SNPs from these genes (Supplementary Table S2 online), including about 2-kb upstream and and 1-kb downstream regions, were chosen from the HapMap database (www.hapmap.org) using a statistical protocol[37] that maximized 'informativeness' of selected SNPs. Individuals belonging to the first HS were genotyped at all the 2488 loci. Genotypes at those loci that showed statistically significant association with AR in the first HS were determined in individuals belonging to the second HS for validation of the discovered associations. Genotyping was done using the Illumina iSCAN (San Diego, CA, USA) platform using Golden Gate assays following protocols recommended by the manufacturer.

Statistical analysis

AR to vaccination was measured as the ratio (fold-change) of Day 28 postvaccination to prevaccination (Day 0) antibody levels (EU/ml). Individuals on whom AR could not be properly assayed (5%) were removed from analyses. Curation of genotype data included removal of (a) loci with $<90\%$ call rate (2% of loci), (b) non-polymorphic loci with MAF<0.05 (12.7% of loci with call rate $>90\%$), (c) loci significantly deviant from HWE (1% of polymorphic loci), and (d) individuals with $<90\%$ of loci with valid genotype calls (0.7%). After data-curation, 948 individuals and 2036 SNPs were included for further analysis. Analysis of variance (ANOVA) was performed to test equality of mean values of *ln*AR ($\log_e$-transformation was used to induce Normality) among subgroups of vaccinees. To avoid detection of spurious associations arising from systematic ancestry differences, population stratification analysis was performed using Eigenstrat.[38] Instead of using an arbitrary threshold to classify a vaccinee as a 'responder' or a 'non-responder', we sorted the vaccinees by ascending order of their AR and grouped the vaccinees into five pentile (20 percentile) groups (PGs). It is expected that the frequency of an allele that is significantly associated with response should increase (or decrease) from low responders to high responders. Detection of allelic association was done by estimating the correlation coefficient (r) between the MAF at each locus and mean AR of vaccinees belonging to the (PGs) and testing H_0: $r=0$ using a permutation test. The false discovery rate procedure[39] was used to identify statistically significant values of r at the 5% level of significance. As correction for multiple testing when loci are in significant linkage disequilibrium (LD) remains a major statistical problem,[40,41] for single-locus association analysis, we circumvented the problem by selecting from each gene only the highly informative and minimally associated SNPs.[37] Four hundred and sixty-nine SNPs were thus selected; data on the remaining loci were kept aside for haplotype association analysis. Each significant allelic association was revalidated by confirming that the null hypothesis that the mean *log*AR values among the genotype classes are equal was rejected, using ANOVA. The standard regression procedure was used to estimate effect size (slope, β) of each significantly associated SNP. SD of effect size was estimated by bootstrapping 100 times; that is, by randomly choosing the appropriate number of samples with replacement from the original data and estimating β from the bootstrap sample and then calculating the empirical SD of the 100 estimates of β. Haplotypes were inferred using Phase.[42] Haplotype association analysis was performed using a permutation algorithm similar to that for single SNP markers.

RESULTS

Demographic characteristics of vaccinees

No statistically significant differences in the demographic characteristics of the vaccinees (Table 1) were noted between the association discovery and validation HSs in respect of age (mean ages were 34.24 ± 0.60 years and 34.36 ± 0.58 years; $p=0.883$), proportions of vaccinees belonging to the two genders ($p=0.602$) or the two religious groups ($p=0.21$).

Inter-individual variation in pre- and post-vaccination antibody levels and AR

Large inter-individual variations of pre- and postvaccination antibody levels and also of AR to vaccination (fold-change) were noted (Table 2 and Supplementary Table S3 online). Mean values between the two HSs were not significantly different (Supplementary Table S3).

Total	323	214	111	163	124	935

χ^2 value = 135.8 (d.f. = 16, $p < 0.0001$).
Contingency coefficient = 0.356 ($p < 0.0001$).

The correlation between baseline and Day 28 antibody levels is positive and moderate (0.449), but significant ($p < 0.0001$).

Antibody response

AR-estimates obtained from the two separate assays were significantly ($p < 0.0001$) correlated (Table 3). As, by its very nature, the vibriocidal assay is less quantitative than the bioplex assay, in further analyses, unless specifically mentioned, AR as measured by the bioplex assay was used. Mean values of *ln*AR for the two HSs did not differ significantly ($p = 0.564$) and were, 1.128 ± 0.038 and 1.160 ± 0.039, respectively. None of the possible covariates–religion, age and gender–had a statistically significant effect on *ln*AR, either individually or interactively (*p*-values for main effects and interactions were all >0.05). Therefore, all data were pooled in subsequent analyses.

Population stratification

No pair of vaccinees in the first HS shared >90% of the 2036 loci with identical genotypes; i.e., there was no evidence of cryptic relatedness among the vaccinees. There was also no evidence of population stratification as all individuals formed a single cluster in the scatterplot of the first three principal components (Figure 1).

Antibody levels and response in vaccinees belonging to the five PGs

Mean values of antibody levels and response were nearly equal for each PG between the HSs (Supplementary Table S4 online), but differed significantly ($P < 0.05$) among the PGs (Table 4). (Mean values of fold-change based on the vibriocidal assay were consistently higher than those based on the bioplex assay.) Mean AR increased almost linearly from PG 1 through 4, after which there was a steep increase (Figure 2), which was also observed for values based on vibriocidal assay. The steep increase of mean AR in PG-5 is primarily because of the presence of some individuals who exhibited very high AR.

Association results: discovery and validation

In the discovery HS, correlations between mean AR and MAFs in PGs were found to be statistically significant at 159 SNP loci on 93 genes (of the 296 genes considered in this study; Supplementary Table S5 online). The associations of these 159 SNPs could be validated in HS-2 only for seven SNPs that are located in and around five genes (rs17180481 and rs17180600 in the flanking region and intron, respectively, of *MARCO* (2q14.2); rs598493 in an intron of *TNFAIP3* (6q23.3); rs3012694 and rs266087 in introns of *RFX3* (9p24.2); rs266087 in an intron of *CXCL12* (10q11.21); and rs6567272 in an intron of *TNFRSF11A* (18q22.1)). Mean AR for vaccinees belonging to the three genotypes for each of these seven SNP loci differed significantly for only the four SNPs in and around *MARCO, TNFAIP3* and *CXCL12* (rs17180481: $p = 0.023$, effect size = 1.8 ± 0.3; rs17180600: $p = 0.026$, effect size = 1.6 ± 0.3; rs598493: $p = 0.001$, effect size = 3.9 ± 0.8; rs266087: $p = 0.014$, effect size = 2.4 ± 0.6), but not for the remaining three. The MAF values in PGs are provided in Figure 3 for these four SNPs.

Haplotype association

For these three genes, data on additional SNPs, which were in significant LD with the SNPs included in the association analysis, were used to reconstruct haplotypes and estimate haplotype frequencies among the vaccinees. Figure 4 provides, for *MARCO, TNFAIP3* and *CXCL12,* the frequency of the haplotype that showed the maximum association with AR by PG. The strength of association (i.e., slope of the line) with AR increased significantly for haplotypes compared with the single SNPs in these genes, indicating that these three genes are important modulators of AR to the vaccine.

Concordance between anti-LPS antibody and vibriocidal responses

For the four loci that were validated to be significantly associated with AR, the proportions of individuals who elicited fourfold or higher

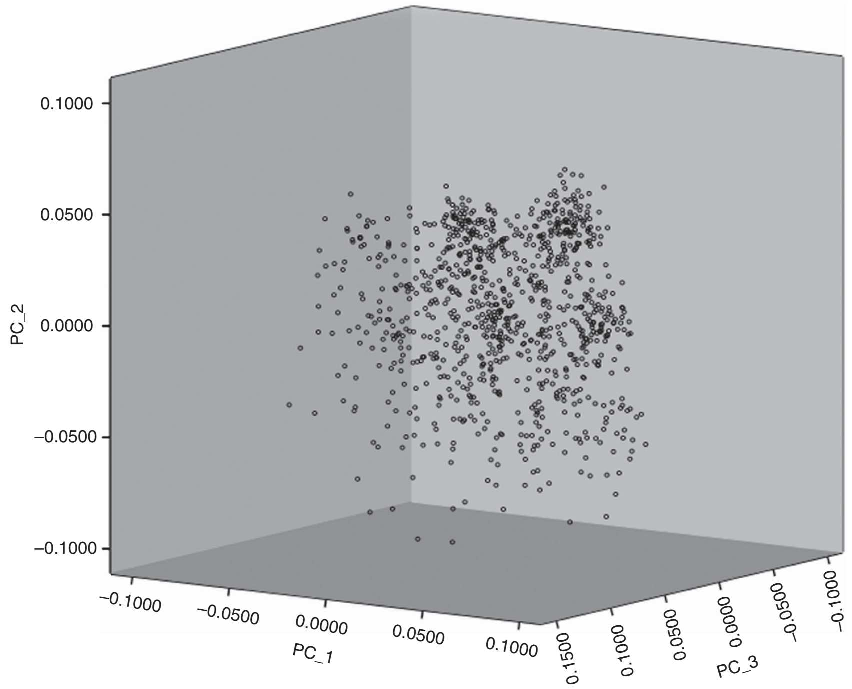

Figure 1 Scatterplot of vaccinees based on first three principal components extracted using data on 2036 SNPs show a single cluster and no evidence of population stratification.

Table 4 Means and SDs of total anti-LPS antibody levels on days 0 and 28, and antibody response, for the five pentile groups based on antibody response

Variable	*Pentile group*	*n*	*Mean*	*SD*
Baseline (Day 0) Antibody level	1	190	41.58	71.51
	2	190	24.10	26.66
	3	190	17.92	21.03
	4	190	17.16	17.56
	5	188	11.82	10.46
	Total	948	22.54	37.95
Day 28 antibody level	1	190	52.61	86.82
	2	190	44.99	52.88
	3	190	46.39	54.48
	4	190	72.73	77.74
	5	188	168.70	190.30
	Total	948	76.89	114.88
Antibody response	1	190	1.31	0.15
	2	190	1.84	0.17
	3	190	2.60	0.28
	4	190	4.20	0.73
	5	188	17.29	24.45
	Total	948	5.42	12.41

titer increase in the vibriocidal assay (that is likely to be suggestive of protective immunity,[43,44] although true protective immunity must be ascertained by vaccine challenge studies) significantly differed among the three genotypes at the locus only for two (rs598493 in *TNFAIP3*; $p=0.001$ and rs266087 in *CXCL12*; $p=0.014$) of these four loci (Figure 5). Thus, although *MARCO* was found to be significantly associated with AR, it was not found to be associated with high vibriocidal titer levels.

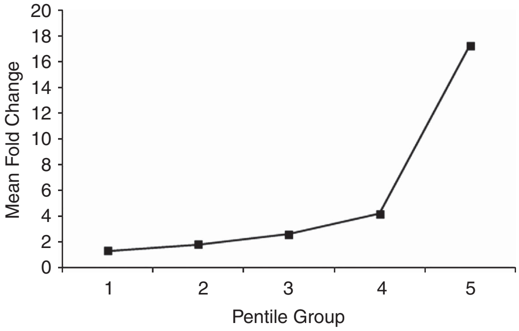

Figure 2 Mean values of antibody response of vaccinees belonging to the five pentile groups.

DISCUSSION

WHO has recommended that cholera vaccination be provided in many geographical regions.[2] Protective immune response to *V. cholerae* that colonizes the intestinal mucosal surface without invasion of enterocytes[45] is believed to reside at the mucosal surface.[44] Orally administered vaccines maximize the intestinal secretory AR, and a long-lasting memory so that the primed intestinal immune system can rapidly respond to a subsequent exposure to antigen.[46] Serum vibriocidal activity, measured by a bactericidal assay requiring the fixation of complement by antibody that is bound specifically to vibrios, is used extensively as a marker of immunity to *V. cholerae*, but has limitations.[47,48] On the basis of

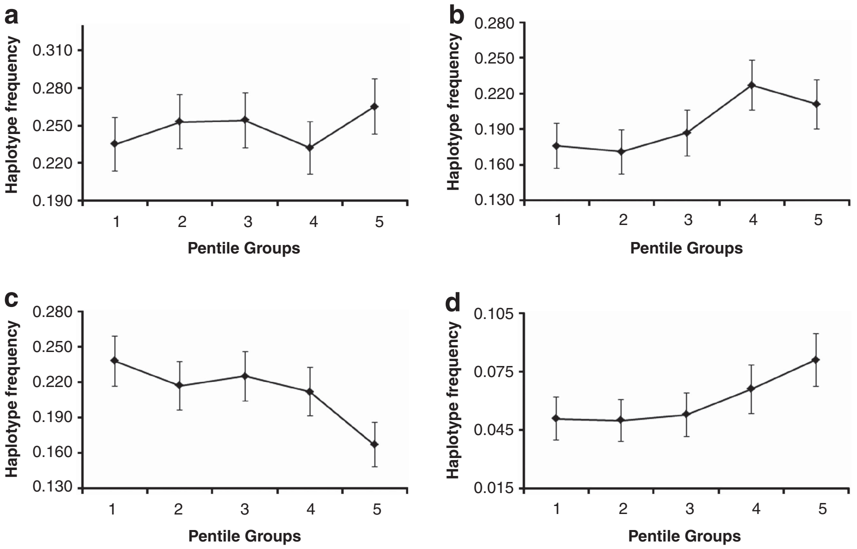

Figure 4 Frequencies of haplotypes containing the minor allele at the significantly associated SNP loci in the pooled sample PGs. (**a**) Haplotype GG**A**GCG of *CXCL12*, (**b**) Haplotype GA**A**GCG of *CXCL12*, (**c**) Haplotype GA**A**GC of *TNFAIP3*, (**d**) Haplotype **AA** of *MARCO*. Boldfaced and underlined alleles are those the minor alleles at the corresponding loci. (Another haplotype–GG**A**GC of *TNFAIP3*–had lower frequencies than those of the haplotype presented in this figure and was absent in three PGs.).

recent reccommendations[49] to measure LPS-response in multiple immunoglobulin isotypes and results[50,51] which indicate that levels of all immunoglobulin isotypes (IgG, IgM and IgA) determine the nature and extent of protection afforded by oral cholera vaccination, we have used the total anti-LPS AR and also the traditional vibriocidal assay.

Clinical trials of many oral vaccines have underscored the importance of understanding the reasons for variability in immune response to oral vaccines,[52] and the identification of genetic factors in the host linked to vaccine immunogenicity. It has been emphasized that such identification may result in adoption of 'inverse of personalized medicine' approaches to design vaccines to overcome barriers in nonresponding populations.[53] Susceptibility to cholera is significantly associated with a marker in the promoter region of *LPLUNC1* (rs11906665),[54] an innate immunity gene that likely has a role in modulating host inflammatory responses to *V. cholerae* infection.[55] We have discovered and validated that three genes–*MARCO*, *TNFAIP3* and *CXCL12*–has significant roles in modulating AR. However, *MARCO* was not significantly associated with increased vibriocidal titers. A single cell layer of the mucosal epithelium

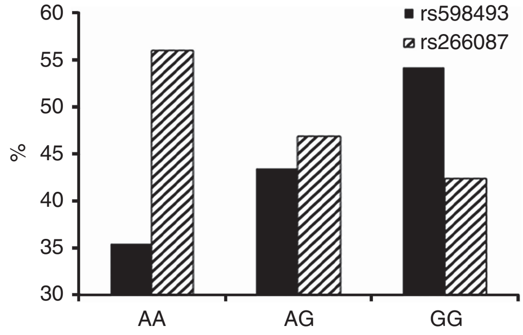

Figure 5 Percentages of vaccinees belonging to the three genotypes which elicited protective vibriocidal response (ie, seroconverted with fold-increase ≥4) upon vaccination for the two loci in *TNFAIP3* (rs598493) and *CXCL12* (rs266087).

essentially regulates intestinal homeostasis. This physical barrier is a prominent part of the innate immune system with damage-healing and infection-limiting properties. *CXCL12* is a homeostatic or constitutive chemokine that has a key role in healing by stimulating the activation of laminin-specific integrins.[56] *V. cholerae* infection produces strong inflammatory manifestations.[57] *CXCL12* is a neutrophil and lymphocyte chemoattractant that is upregulated in response to *V. cholerae* infection, resulting in increased recruitment of polymorphonuclear leukocytes to the site of infection.[58] The LPS in the cholera vaccine possibly provides signals that mimic those of the live bacterium, without actually causing disease. The TNF-induced protein 3 (*TNFAIP3*) is an ubiquitin-modifying enzyme and an essential negative regulator of inflammation, through the inhibition of NF-κB activation and prevention of TLR-mediated responses.[59] Tight junctions between intestinal epithelial cells mediate the permeability of the intestinal barrier. *TNFAIP3* has a role in promoting intestinal epithelial barrier integrity and in enabling maintenance of intestinal homeostasis through tight junction protein regulation;[60] possible requirements for adequate response to the whole-cell killed cholera vaccine used in this study. *TNFAIP3* has also been implicated in genome-wide studies of susceptibility of several autoimmune disorders.[61] *MARCO* is a type II transmembrane protein of the class A scavenger receptor family.[62] LPS, the major component of the vaccine used in this study, is a very potent activator of innate immune responses. LPS stimulation upregulates surface expression of *MARCO* in a dose- and time-dependent fashion.[63] *MARCO* is upregulated in bacterial infections in macrophages of most tissues; variants in this gene have crucial roles in bacterial binding.[64] No SNP in *MARCO* was found to be associated with high vibriocidal titer, possibly because different immunoglobulin isotypes are associated with anti-LPS and vibriocidal responses.[65]

The inferences of this study carried out in a cholera-endemic area, where many vaccinees possibly have prior exposure to the pathogen and consequently have high-baseline antibody levels (Table 2), may require validation in a non-endemic area. We, however, emphasize that the vaccine-response studies are more relevant and meaningful from a public-health viewpoint if conducted in endemic areas. In individuals with prior exposure to *V. cholerae*, the administered vaccine possibly acted as a booster, implying that individuals with high-baseline antibody levels are expected to show a low response (fold-change) to the vaccine, while individuals with low-baseline antibody levels are expected to show a high response. Although this feature was weakly observed (Table 2), the Day 0 and Day 28 antibody levels were significantly ($P<0.0001$) positively correlated ($r=0.449$). In this study we have used quantitative level of AR. Therefore, genomic associations with antibody fold-change detected in this study are unlikely to be affected by baseline antibody levels. However, it may be tricky is to relate the association between the level of AR and a SNP in a gene of the immune system with the level of immunological protection. In an endemic area, individuals with the lowest AR may be the best protected, while in a non-endemic area the reverse may be true. Although these issues pertaining to long-term protection remain unresolved, the genes that have shown significant association with AR are all biologically relevant. Functional studies on the markers found to be associated with AR need to be carried out, which together with the findings on *LPLUNC1*,[54,55] may provide a deep mechanistic understanding of the mode of action of the whole-cell killed oral cholera vaccine.

CONFLICT OF INTEREST

The authors declare no conflict of interest.

ACKNOWLEDGEMENTS

Financial support for this work was provided by U.S. National Institute of Allergy and Infectious Diseases, National Institutes of Health Contract HHSN200400067C. The vaccine was used in this study with approval of the Drug Controller General of India, and the entire study was approved by the Health Ministry Monitoring Committee, Government of India; we are grateful to them for the approvals. We are grateful to members of CpG and TCGA for their expert help in the conduct of this project.

Salmonella enterica is one of the most important foodborne pathogens around the world. In the last years, *S. enterica* serovar Infantis has become an important emerging pathogen in many countries, often as multidrug resistant clones. To understand the importance of *S. enterica* in the broiler industry in Ecuador, we performed a study based on phenotypic and WGS data of isolates from poultry farms, chicken carcasses and humans. We showed a high prevalence of *S. enterica* in poultry farms (41.4%) and chicken carcasses (55.5%), but a low prevalence (1.98%) in human samples. *S.* Infantis was shown to be the most prevalent serovar with a 98.2, 97.8, and 50% in farms, foods, and humans, respectively, presenting multidrug resistant patterns. All sequenced *S.* Infantis isolates belonged to ST32. For the first time, a pESI-related megaplasmid was identified in Ecuadorian samples. This plasmid contains genes of antimicrobial resistance, virulence factors, and environmental stress tolerance. Genomic analysis showed a low divergence of *S.* Infantis strains in the three analyzed components. The results from this study provide important information about genetic elements that may help understand the molecular epidemiology of *S.* Infantis in Ecuador.

Keywords: *Salmonella* Infantis, ST32, broiler, WGS, Ecuador, megaplasmid, multidrug resistance (MDR)

INTRODUCTION

Foodborne infections caused by *Salmonella enterica* are of primary importance worldwide. The WHO estimates that *Salmonella* causes more than 153 million illnesses, 120,281 deaths, and 8.27 million disability-adjusted life years annually (1). As foodstuffs can be contaminated in several parts of the food chain, a "from farm to table" approach is necessary to understand the epidemiology of *Salmonella*. Although *Salmonella* can contaminate vegetables, food-producing animals, especially poultry, are considered important sources for human infections (2, 3). In Latin American countries, poultry is one of the main sources of protein of animal origin. This is the case of Ecuador, where poultry meat is the most consumed commodity with a yearly per capita consumption of 30.4 Kg (4).

Previous investigations in Latin America showed that *Salmonella enterica* serovar Infantis is an increasingly important serotype on poultry farms (5–9). Moreover, this serotype has also been reported to cause infections in local inhabitants and travelers that have visited Latin American countries (10–12). However, no genomic data considering isolates of *Salmonella* originated from animals, foodstuff, and humans have been released in Latin America so far.

Antimicrobials are commonly used in poultry production as both therapeutics and growth promoters. However, even when antimicrobials are used under technical criteria, they can select resistant strains of *Salmonella* that pose a public health problem when reaching consumers (13). This is of special concern in developing countries where the misuse of antimicrobials and lack of control is an issue to be addressed.

There is a wide diversity of virulence factors that are essential for pathogenicity of *Salmonella* in host cells. Among these factors, fimbriae, flagella, plasmids, pathogenicity islands, toxins, and secretion systems are the more frequently associated to pathogenic strains of *Salmonella* (14).

This research was aimed at describing by phenotyping methods and whole-genome sequencing, the antimicrobial resistance (AMR) characteristics and genetic profiles of *Salmonella* isolates obtained from broiler farms, broiler carcasses and humans in Quito—Ecuador.

MATERIALS AND METHODS

Study Design and Sampling

Samples for *Salmonella* isolation were collected weekly from November 2017 to November 2018 following the guidelines of the document: "Integrated Surveillance of Antimicrobial Resistance in Foodborne Bacteria" by the World Health Organization (15).

Poultry Farms: 133 flocks from 69 farms were sampled during the study period. For every sampled flock, 25 caeca from 25 chicken were randomly collected at the slaughterhouse level and transported to the laboratory in an ice-box within the next 2 h. Caecal samples are recommended by the WHO because they provide a higher recovery of isolates and better represent contamination of individual animals at the farm level (15). At the laboratory, a sample pool of 25 g was obtained for bacteriological isolation as previously described (8).

Chicken carcasses: 335 carcasses were collected in three kinds of markets as follows: 125 samples from supermarkets, 126 samples from small shops, and 84 samples from open markets. Sampling of chicken carcasses was performed alternately between the north and south of the city. Each carcass was collected in its original bag and transported to the laboratory in an ice-box within the next 2 h. At the laboratory, 25 g of breast skin of every carcass were aseptically collected for bacteriological analysis.

Human stool samples: 302 samples were evenly collected in two health care centers located in the urban periphery of Quito (Guamani health care center at the south and Calderon health care center at the north) from patients with two or more episodes of diarrhea or vomiting in the last 24 h. Human stool samples were transported to the laboratory in an ice-box within the next 2 h. Approximately 25 g of feces were collected for bacteriological analysis.

According to national legislation, ethics approval was not required for poultry farms and chicken carcasses sampling since no animals were sacrificed during this study. For the human component, the project was approved by the bioethics committee from the National Institute of Public Health "Leopoldo Izquieta Pérez" (Protocol ID:CEISH-INSPI-005). The participants were informed about the objective of the study and all volunteers provided a written consent. All personal information was anonymized.

Isolation and Identification of *Salmonella enterica*

Salmonella isolation was performed by a method based in the ISO 6579-1:2007 protocol. Briefly, 225 mL of Buffered Peptone Water (BPW; Difco, BD, Sparks, MD) was added to every sample, homogenized by hand for 1 min and incubated at 37°C for 20 h. Then, 100 μL of each enrichment was inoculated onto Modified Semi-solid Rappaport-Vassiliadis agar (MSRV; Oxoid, Basingstoke, UK) in three equidistant points and incubated at 42°C for 24 h. Afterwards, plates were examined for the presence of a white halo around of at least one inoculation point. A loopful taken from the edge of the white halo was streaked on a Xylose Lysine Deoxycholate agar (XLD, Difco) and incubated at 37°C for 24 h. After incubation, one suspect colony of *Salmonella* was biochemically confirmed by Triple Sugar Iron (TSI, Difco, BD), Iron Lysine (LIA, BBL, BD), Urea (BBL, BD), and Sulfur Indole Motility tests (SIM, BBL, BD). Isolated colonies were confirmed by PCR as previously described (16). The 95% confidence interval ($CI_{95\%}$) for the prevalence of *Salmonella* at each component was calculated.

Antimicrobial Susceptibility Testing

All *Salmonella* isolates were examined by the Kirby-Bauer disk diffusion method with the following antibiotics: sulfamethoxazole + trimethoprim (25 μg), gentamicin (10 μg), ciprofloxacin (5 μg), cefotaxime (30 μg), tetracycline (30 μg), streptomycin (10 μg), chloramphenicol (30 μg), cefoxitin (30 μg), amikacin (30 μg), nitrofurantoin (300 μg), azithromycin (15 μg), fosfomycin (200 μg), ertapenem (10 μg), amoxicillin + clavulanic acid (30 μg). *E. coli* ATCC 25922 strain was used as quality control. Results and methods were interpreted according to CLSI 2019 criteria considering all intermediate phenotypes as resistant for further analysis (17).

Detection of Extended Spectrum Beta-Lactamase (ESBL) Genes

Salmonella isolates that presented resistant phenotypes to beta-lactam antibiotics were further tested by PCR for the identification of ESBL genes. PCR conditions and primers were the ones described by Hasman et al. (18) for bla_{CTX-M}, Olesen et. al (19) for bla_{TEM}, Kruger et al. (20) for bla_{CMY} and Arlet et al. (21) for bla_{SHV}. Sub-families of bla_{CTX-M} genes were identified with PCR protocols described by Carattoli et al. (22) for $bla_{CTX-M-1}$, Jiang et al. (23) for $bla_{CTX-M-2}$, Hopkins et al. (24) for $bla_{CTX-M-8}$, Paauw et al. (25) for $bla_{CTX-M-9}$ and

Dierikx et al. (26) for $bla_{CTX-M-14}$. Amplification products were confirmed by gel electrophoresis using a 2% agarose gel. All PCR products were purified and sequenced at Macrogen Inc (Seul-South Korea). Obtained sequences were aligned against reference sequences with the online tool ResFinder v3.2 (27).

Whole Genome Sequencing

For whole genome sequencing (WGS), a selection of *Salmonella* isolates was made from the animal and food components. When selecting isolates from poultry farms the first positive sample of each farm was considered. For chicken carcasses, the first positive sample of every sampling week in each kind of market was selected. All non-*S.* Infantis isolates and all isolates from the human component were selected for WGS.

Genomic DNA was extracted using Invitrogen PureLink Genomic DNA Kit (Thermo Fisher Scientific, Walthman, MA, USA) following manufacturer's recommendations for Gram-negative bacterial cell lysates. DNA was quantified using Invitrogen Qubit 3.0 fluorometer (Thermo Fisher Scientific, Walthman, MA, USA), and sequenced with the Illumina NextSeq platform using Nextera XT Library Preparation Kit obtaining 150 × 2 bp paired-ends sequences (Illumina, San Diego, CA, USQ). Default parameters were used for all bioinformatic tools and programs unless otherwise specified. Reads were trimmed with Trimmomatic to remove ambiguous nucleotides and those with quality score values <20 (28). The programs Fastqc (29) and Multiqc (30) were used for quality assessment.

Serotype Identification

Salmonella serotypes were identified by PCR as described by Akiba et al. (16). Additionally, serotypes of isolates subjected to WGS were further confirmed by the analysis of their raw sequencing reads using the SeqSero pipeline (31).

MLST Analysis, Antimicrobial Resistance Genes, and Plasmid Detection

In order to identify MLST sequence types (ST), antimicrobial resistance genes and plasmid sequences, ARIBA (32) was used with PubMLST (33), ResFinder v3.2 (27), and PlasmidFinder 2.1 (34) databases, respectively. Phenotype resistance was compared with the presence of resistance genes found by WGS. Additionally, we performed a mapping against the megaplasmid p-F219 described by Vallejos-Sánchez et al. (35) using Burrows-Wheeler Aligner with BWA-MEM algorithm (36). BCFtools and vcfutils from SAMtools (37) were used to obtain the fastq files from SAM files, and the fasta sequences were transformed from fastq with Seqtk (38). The sequences were concatenated and a maximum likelihood phylogenetic tree was obtained with IQTREE2 software (39). As we obtained two well-defined clusters for *S.* Infantis, we annotated one representative of each plasmid cluster with Prokka (40) and performed an orthologous genes analysis (coverage of 90%, similarity on protein sequences of 80%) with Proteinortho5 (41). A manual comparison of all genes present in the plasmids was carried out. We performed the same analysis for non-Infantis isolates.

Megaplasmid Analysis

Two megaplasmids (pESI and p-F219) commonly associated to pathogenic and MDR strains of *S.* Infantis were analyzed in order to identify their relatedness. We used D-Genies (42) to obtain a dot plot of genome comparison, a genome alignment with progressiveMauve (43) in order to identify locally collinear blocks, and an ANI calculation (44) for computing average nucleotide identity in sequences shared by both plasmids.

Core Genome and Metadata Analysis

A Peruvian *S.* Infantis strain, FARPER-219 (35), and two Ecuadorian isolates (SRR4019589 and SRR4019602) analyzed by the US Centers for Disease Control and Prevention from two patients that developed salmonellosis after traveling to Ecuador (10) were added as references in the phylogenetic analysis of all *S.* Infantis isolates. From trimmed reads, Spades (45) was used to generate assemblies. Later, genome annotation was performed with Prokka (40). An orthologous genes analysis with the same conditions as for plasmid detection was performed with Proteinortho5 (41). The strict core genes, those present in all the isolates, were extracted with the Proteinortho tool: grab_proteins.pl. Mafft (46) and an in-house script were used for multiple alignment of every gene and subsequent concatenation in a single multiple alignment, respectively. The phylogenetic tree from the core genome alignment was obtained using IQTREE2 (39) with 1,000 bootstrap replicates. The metadata for sample origin, phenotypic antibiotic resistance patterns, and plasmid *in silico* detection was added to the final tree with iTol tools (47).

RESULTS

Salmonella Prevalence and Serotype Identification

Salmonella was present in 41.4% (55/133; $CI_{95\%}$:33–49.7), 55.5% (186/335; $CI_{95\%}$:50.2–60.8), and 1.98% (6/302; $CI_{95\%}$:0.4–3.6) in poultry farms, chicken carcasses and human stool samples, respectively. *S.* Infantis accounted for 98.2% ($n = 54$) of isolates from poultry farms, 97.8% ($n = 182$) of isolates from chicken carcasses, and one half ($n = 3$) of human sample isolates. Additionally, one isolate was typed as *S.* Enteritidis in broiler flocks; at the retail level one and three isolates were typed as *S.* Typhimurium and *S.* Enteritidis, respectively, while in the human stool samples two isolates were typed as *S.* Enteritidis and one isolate corresponded to monophasic *S.* Typhimurium 4,[5],12:i:- (**Supplementary Table 1**).

Antimicrobial Resistance

For *S.* Infantis isolates, antimicrobial resistance rates to nitrofurantoin, tetracycline, sulfamethoxazole + trimethoprim, streptomycin, gentamicin, cefotaxime, ciprofloxacin and chloramphenicol ranged from 64.8 to 100%. On the other hand, fosfomycin and azithromycin resistance rates were lower, ranging from 0 to 42.6%. Only one isolate from a stool sample presented phenotypic resistance to amikacin while none of the *Salmonella* isolates in this study was resistant to ertapenem (**Table 1**).

TABLE 1 | Number of *S*. Infantis isolates resistant to each tested antimicrobial.

Antimicrobial	**Number (%) of resistant isolates**		
	Poultry farms (farm)	**Chicken carcasses (food)**	**Stool samples (human)**
Nitrofurantoin	54 (100)	180 (99.4)	2 (66.7)
Tetracycline	54 (100)	176 (97.2)	3 (100)
Sulfamethoxazole + trimethoprim	44 (81.5)	158 (87.3)	1 (33.3)
Streptomycin	46 (85.2)	154 (85.1)	3 (100)
Gentamicin	45 (83.3)	155 (85.6)	2 (66.7)
Cefotaxime	51 (94.4)	150 (82.9)	1 (33.3)
Chloramphenicol	45 (83.3)	149 (82.3)	2 (66.7)
Ciprofloxacin	35 (64.8)	116 (64.1)	1 (33.3)
Fosfomycin	23 (42.6)	68 (37.6)	1 (33.3)
Azithromycin	10 (18.5)	31 (17.1)	0 (0)
Cefoxitin	7 (13)	11 (6.1)	0 (0)
Amoxicillin + clavulanic acid	7 (13)	7 (3.9)	0 (0)
Amikacin	0 (0)	0 (0)	1 (33.3)
Ertapenem	0 (0)	0 (0)	0 (0)

**1 isolate obtained from poultry farms and 2 isolates from human stool samples. Sulfonamide (S), aminoglycosides (A), quinolones (Q), Beta-lactams (B), tetracyclines (T), phenicol (F), nitrofuran (N), macrolides (M), Fosfomycin (P).*

Considering antimicrobial classes that were tested, *S*. Infantis isolates presented 43 antimicrobial resistance patterns. With the exception of one isolate from a stool sample, all isolates showed multidrug-resistant phenotypes. Importantly, 87 and 82% of isolates from poultry farms and chicken carcasses, respectively, presented resistance from 6 up to 9 classes of antimicrobials (**Supplementary Table 2**). One *S*. Infantis isolated from chicken carcasses could not be recuperated for this analysis.

Salmonella serotypes other than *S*. Infantis also presented multiresistant patterns, except for 3 *S*. Enteritidis isolates that were only resistant to one group of antimicrobials. For this set of isolates, every resistant pattern included isolates belonging to only one serotype (**Table 2**).

One isolate of *S*. Enteritidis, one of *S*. Typhimurium and one of Monophasic *S*. Typhimurium 4,[5],12:i:-; and 205 isolates of *S*. Infantis were identified as resistant to beta-lactam antibiotics.

Six *S*. Infantis isolates from chicken carcasses and one from poultry farms did not present any of the investigated ESBL genes. All other *S*. Infantis and one *S*. Enteritidis isolated from a carcass presented the $bla_{\mathrm{CTX-M-65}}$ gene.

Genomic Analysis

For WGS analysis, 144 isolates (40 from the animal component, 98 from the food component and six from the human component) were selected. Raw sequence data is available under bioproject PRJEB37560. The sequences from three samples were not enough to perform genomic analysis. The obtained average number of reads per strain was 1,356,678 (range 247,022–14,106,025) and after the quality control steps, the average number was 1,266,242 (range 228,263–13,094,594) (**Supplementary File 1**). Average Phred Score was Q34.

MLST typing showed that all *S*. Infantis isolates ($n = 137$) belonged to ST32. The five *S*. Enteritidis isolates belonged to ST11. Additionally, the single isolates of *S*. Typhimurium and monophasic *S*. Typhimurium 4,[5],12:i:- belonged to ST19 and ST2379, respectively (**Supplementary Table 1**).

The strict core genome of all *S*. Infantis included in the analysis corresponded to 3,552 genes and spanned 3,161,448 bp, 1,414 of which were variable (SNPs). The alignment of the concatenated genes present in this core was used to obtain a maximum-likelihood tree using FARPER 219 as outgroup (**Figure 1**). This strain was chosen because it was isolated in Peru, a neighbor country to Ecuador. Despite its inclusion in ST32, FARPER-219 presented genetic divergence with the Ecuadorian strains. The two *Salmonella* genomes from the USA (SRR4019589, SRR4019602) grouped indistinctive with some of the genomes of this study. Notably, the analyzed strains did not group according to their sampling origin or their phenotypic resistance patterns.

Genes of antimicrobial resistance were also confirmed with WGS data (**Supplementary File 2**). For most of the antimicrobial classes (folate pathway inhibition, aminoglycoside, beta-lactams, tetracyclines, fosfomycin, and phenicol) correspondence rates were higher than 80%. However, no genes responsible for the phenotypic resistance to quinolones, nitrofurans, and macrolides were found in sequenced isolates (**Table 3**).

Regarding virulence genes, *sifA, sseL, pipB, sopD2,* and *srlP* (part of SPI 2) were found in the core genome of all *S*. Infantis strains. The *lpf* operon that encodes the long polar fimbrae (LPF), the *fim* gene cluster that encodes type 1 fimbriae, and the *csg* operons that encodes the Tafi fimbriae (Thin aggregative fimbriae) were also present in these genomes.

The presence of plasmids was confirmed *in silico* by PlasmidFinder. Only one *S*. Infantis isolate (U2449s) presented one plasmid determinant (IncX1 and IncX1_1) despite the multidrug resistance patterns found in our isolates (**Figure 1** and **Supplementary File 2**). To further analyze the low incidence of plasmids, we mapped the raw reads from our samples against the megaplasmid p-F219 described by Vallejos-Sánchez et al. (35). We found two p-F219-like plasmids. The first one,

FIGURE 1 | Maximum likelihood phylogenetic tree of core genome alignment of all 137 *S.* Infantis isolates based on 3,552 genes. Two *S.* Infantis genomes from Ecuador detected in USA (SRR4019589, SRR4019602) and a Peruvian strain (FARPER-219) were included in the analysis and are indicated with a black triangle. The origin of each sample is colored in red for human stool samples, in green for poultry farms isolates and in orange for chicken carcasses strains. The phenotypic resistance for nine antibiotic families is marked with a blue box. Strains with p-F219-like plasmid B are marked with a red star. The rest of the samples harbor the p-F219-like plasmid A. The purple star indicates the presence of IncX1 and IncX1_1 plasmids in one of the strains. Digital version of the phylogenetic tree is available with iTOL login LMejia at https://itol.embl.de/shared_projects.cgi.

denoted as plasmid A, was present in most of the strains. This plasmid contained 338 genes shared with the p-F219 megaplasmid. The second one, denoted as plasmid B, was present in the remaining seven strains. Plasmid B lacked 72 of the genes present in plasmid A and presented six exclusive genes (**Supplementary File 3**). The strains that presented plasmid B belonged to a monophyletic clade (denoted with a red star in **Figure 1**). These strains also share susceptibility to fosfomycins, macrolides, phenicols, and beta-lactams. *Salmonella* strains harboring plasmid B were isolated from chicken carcasses sampled during different weeks of the year, different parts of the city and different types of retail stores (data not shown).

New hypothetical proteins ($n = 147$) were found in both plasmids; 43 exclusively found in plasmid A and five in plasmid B (**Supplementary File 3**).

The comparison of the p-F219 plasmid with another megaplasmid, commonly found in pathogenic *S.* Infantis strains, pESI plasmid, showed that they share more than 79% of their sequences (>75% of identity) (**Supplementary Figure 1**). Besides, we noticed a large genomic inversion in plasmid p-F219 when compared with the pESI plasmid that is also observable in progressiveMauve genome alignment (**Supplementary Figure 2**). From the ANI calculation, 99.41% of identity was found in the orthologous genes present in both samples.

TABLE 3 | Comparison of phenotypic AMR with AMR genes obtained from WGS data.

Antibiotic family	Phenotype (%)[a]	Phenotype + AMR gene[b] (%)	No phenotype + AMR gene[c] (%)
Folate pathway inhibition	84.56	92.17	7.83
Aminoglycoside	97.06	100	3.03
Quinolone	58.09	1.27	0
Beta-lactams	84.56	94.87	4.27
Tetracycline	97.06	99.24	0.76
Phenicol	80.88	80.91	6.36
Nitrofuran	98.53	0	0
Macrolide	17.65	0	0
Fosfomycin	37.5	90.2	41.18

[a] *Rate of isolates with phenotypic resistance.*

[b] *Rate of isolates with phenotypic resistance that presented a resistance gene by WGS analysis.*

[c] *Rate of isolates without phenotypic resistance that presented a resistance gene by WGS analysis.*

In silico plasmid detection in non-Infantis isolates showed the presence of two plasmids in all *S.* Enteritidis strains, while monophasic *S.* Typhimurium 4,[5],12:i:- and *S.* Typhimurium presented 1 and 5 plasmids, respectively (**Supplementary Table 1**).

DISCUSSION

In the last decades, there has been a clear rise in the prevalence of multidrug resistant *Salmonella enterica* worldwide, especially of serovar Infantis (11, 48–50).

To better explain the epidemiology of *Salmonella* in Ecuador, we studied *S. enterica* isolated from poultry farms, chicken carcasses and human stool samples in Quito. The prevalence of *Salmonella* was high in poultry farms and chicken carcasses, similarly to other studies in the region (6–8, 51). Although this research did not look for *Salmonella* in earlier stages of the broiler production chain, previous studies in Ecuador have reported the importance of compound feed, 1-day-old chicks and broiler pens in the *Salmonella* exposure of broilers (7, 52). These results highlight the necessity to improve broilers production systems in Ecuador toward a better control of *Salmonella* in the food chain.

In this study, it was also seen that samples from different kinds of markets delivered similar rates of *Salmonella* isolates, denoting that the geographical distribution of retailers does not influence the presence of *Salmonella* in carcasses (**Supplementary Table 3**). On the other hand, all human isolates originated in the southern health care center. However, it must to be considered that the low *Salmonella* prevalence in human samples could be influenced by the fact that other pathogens might be the main causes of diarrhea. This fact has been studied in Ecuador were other viruses, parasites and bacteria are the main cause of gastroenteritis cases (53–56). Additionally, the state of health carriers should be considered when accessing the real prevalence of *Salmonella* in humans (57). These circumstances represent limitations of this study and should be considered in future research.

The predominance of *S.* Infantis in this study is in accordance with other reports in the world that show that this serotype is becoming an emergent pathogen. For example, in Europe, *S.* Infantis has been reported to be one of the most common serovars in poultry and in humans (58). The same tendency has been reported in the neighboring country of Peru, where *S.* Infantis is the most prevalent serotype in broilers (6). However, a wider variety of serotypes has been reported in other Latin American countries (51, 59, 60). This could be explained by the fact that the poultry industry of Peru and Ecuador have close commercial interactions which could determine a common epidemiology of this pathogen. Nevertheless, a recent publication from Chile reported that 24% of broiler meat samples ($n = 361$) were positive to the isolation of *S.* Infantis (61). This data highlights the necessity of more research in the field to better understand the epidemiology of *Salmonella* in the region.

Several studies have shown that control programs of targeted *Salmonella* serotypes could have favored the occurrence of other serotypes (2, 62). This kind of shifts might explain to some extent the low presence of *S.* Enteritidis and Typhimurium among our samples but further research is needed to prove this hypothesis.

Most *Salmonella* isolates in this study presented multidrug resistance (MDR) phenotypes. This issue is especially evident in *S.* Infantis, as already been seen in Ecuador (7, 8) and other countries of the region (63–65). Although in a lower extent, this feature has also been reported in Europe where high rates of MDR (up to 85%) are reported in *S.* Infantis isolated from poultry (66). The high levels of resistance in *Salmonella* isolates in Latin America could be related to the intensive use of antimicrobials in poultry production as prophylactics, therapeutics, and growth promotors (67, 68).

S. Infantis isolates belonged to ST32, that is among those more frequently identified within this serovar (33, 69). All Ecuadorian *S.* Infantis isolates showed a high genomic similarity with an apparently common origin. However, in order to verify that all in fact share a common ancestor, a larger analysis including isolates from countries around the world is necessary for identifying the origin of this serovar in Ecuador. The close similarity found between isolates from farms, animals and humans show that this pathogen may be responsible for human infections through the food chain.

We did not observe any clear clustering of *S.* Infantis isolates and antibiotic phenotypic resistance patterns, what makes sense since the phylogenetic tree was obtained from the core genome and most of the antimicrobial resistance determinants are expected to be part of the accessory genome.

The resistance genes analysis carried out here could not successfully explain resistance to macrolides, nitrofurans, and quinolones in our isolates. In fact, phenotypic patterns and genetic detection correlation differences have been described previously (70–72), but point mutations not considered in this study may explain these phenotypes. Additional studies are still needed in order to identify the genes or mutations responsible for antimicrobial resistance in *S.* Infantis.

We found two p-F219-like plasmids (named A and B) present in all the analyzed isolates. Our samples share a significant number of genes with the p-F219 plasmid. The similarity between both p-F219-like plasmids requires a recent common ancestor from which they may have evolved. These plasmids may provide fitness and pathogenic advantages to the strains since they contain several genes for antimicrobial resistance, fimbriae, transposases, and environmental stress tolerance (**Supplementary File 3**). Other *S.* Infantis isolates around the world have been shown to also harbor pESI-related megaplasmids, that appear to be the difference between non-pathogenic and pathogenic isolates since it also provides antimicrobial resistance, oxidative stress tolerance, pathogenicity traits, and mercury environmental tolerance (69, 70, 73, 74). Besides, pESI has shown more pathogenicity and increased intestinal inflammation in experimental mice infections when compared to the plasmid-free isolates (73).

Both plasmids (p-F219 and pESI) share regions of very close similarity with an extensive genomic inversion. Genes present in both plasmids share more than 99% average nucleotide identity suggesting that p-F219 is actually a pESI-like plasmid and the variants found in our samples may also be cataloged as such. A genomic comparison between *S.* Infantis strains showed that large plasmids from multiple isolates actually share a pESI backbone with some genetic plasticity to add different mobile genetic elements due to insertion sequences (75). As pESI-like plasmids confer a MDR phenotype but also several virulence factors and tolerance to environmental stress, their acquisition may have been involved for making *S.* Infantis a successful emerging pathogen worldwide.

The negative results from the unmapped reads from *S.* Enteritidis and *S.* Typhimurium isolates against the p-F219 plasmid suggest that this plasmid may not be widespread among other *Salmonella* serovars, but more isolates need to be analyzed to confirm this hypothesis.

Other virulence genes in *Salmonella* are essential for pathogenicity and infection. We looked for some of the more relevant virulence and invasion determinants in the core genome of *S.* Infantis as determined by ProteinOrtho. Some genes that are usually identified as part of the *Salmonella* pathogenicity island 2 (SPI-2) were found: *sifA, sseL, pipB, sopD2, srlP* (75). The long polar fimbrae (LfP), encoded by the *lpf* operon, was found as putative proteins in all isolates; it is believed that this protein is involved in adhesion and growth on the small intestine mucosa (76), evasion of the host immune system (77). Moreover, variations in these genes may also impact the host range of the bacteria (78). We also found the *fim* gene cluster that encodes type 1 fimbriae and it is involved in the initiation of biofilm formation (79). Another determinant found in our strains was the *csg* operon that encodes the Tafi fimbriae (Thin aggregative fimbriae). Tafi is responsible of adhesive activities and biofilm formation (76). The presence of these genes in *S.* Infantis may suggest a pathogenic character of this serotype that, together with the multidrug resistant profiles, represent a potential public health concern.

To the best of our knowledge this is the first report based on *Salmonella enterica* in Ecuador that uses phenotypic and WGS information to analyze the relatedness of strains isolated from poultry, food and human samples. Isolates from this study show multidrug resistance patterns highlighting the importance of a reduced and better usage of antimicrobials in intensive poultry farms settings. Presence of related megaplasmids together with the core genome high similarity may suggest the dissemination of *S.* Infantis through the food chain to humans. The data presented here has shown the importance of *Salmonella enterica* serovar Infantis as a foodborne pathogen in Ecuador and provide critical information about its clonality and circulating strains.

DATA AVAILABILITY STATEMENT

Sequence data are available under bioproject PRJEB37560.

ETHICS STATEMENT

According to national legislation, ethics approval was not required for poultry farms and chicken carcasses sampling since no animals were sacrificed during this study. For the human component, the project was approved by the bioethics committee from the National Institute of Public Health Leopoldo Izquieta Pérez (Protocol ID was CEISH-INSPI-005). The participants were informed about the study's objective and all volunteers provided a written consent. All personal information was anonymized.

AUTHOR CONTRIBUTIONS

JM, JW, FV, and CV-B conception and design of the study. JLM, CS, FV, and RB performed laboratory analysis. JLM and CV-B performed the statistical analysis. JLM, LM, and CV-B organized the databases. LM and FG-C performed the bioinformatic and genomic analysis. CV-B and LM wrote the first draft of the manuscript. LM, SZ, FG-C, and CV-B contributed to the manuscript revision. All authors contributed to the article and approved the submitted version.

FUNDING

This project was funded by the WHO Advisory Group on Integrated Survillance on AMR (AGISAR) grant AGISAR-JM/lg and also funded by projects BFU2017-89594R from MICIN (Spanish Government) and PROMETEO2016-0122 (Generalitat Valenciana, Spain). WGS was co-financed by the European Union through the Operational Program of European Regional Development Fund (ERDF) of Valencia Region (Spain) 2014–2020. LM was recipient of a predoctoral fellowship from Fundación Carolina and Universidad San Francisco de Quito.

ACKNOWLEDGMENTS

Our acknowledgments to Dr. Gina Watson and Dr. Aida Soto from the OPS/OMS Ecuadorian office for the support in the logistical management of this project. We also thank Mariuxi Japon and Paola Damian for their support with the laboratory work and isolation of *Salmonella*. Whole genome sequences were obtained at Servicio de Secuenciación y Bioinformática (FISABIO, Valencia). Action co-financed by the European Union through the Operational Program of European Regional Development Fund (ERDF) of Valencia Region (Spain) 2014–2020.

TYPE 2 DIABETES, THOUGH POORLY UNDERSTOOD, IS KNOWN TO BE A DISease characterized by an inadequate beta-cell response to the progressive insulin resistance that typically accompanies advancing age, inactivity, and weight gain.[1] The disease accounts for substantial morbidity and mortality from adverse effects on cardiovascular risk and disease-specific complications such as blindness and renal failure.[2] The increasing global prevalence of type 2 diabetes is tied to rising rates of obesity[2] — in part a consequence of social trends toward higher energy intake and reduced energy expenditure. However, the mechanisms that underlie individual differences in the predisposition to obesity remain obscure.

Failure to understand the pathophysiology of diseases such as type 2 diabetes and obesity frustrates efforts to develop improved therapeutic and preventive strategies. The identification of DNA variants influencing disease predisposition will, it is hoped, deliver clues to the processes involved in disease pathogenesis. This would not only spur translational innovation but also provide opportunities for personalized medicine through stratification according to an individual person's risk and more precise classification of the disease subtype. In this article, I consider the extent to which these objectives have been realized.

DISCOVERY OF SUSCEPTIBILITY GENES

For type 2 diabetes and obesity, the discovery of causal genes (Fig. 1 and 2) has followed three main waves. The first wave consisted of family-based linkage analyses (see the Glossary) and focused candidate-gene studies. These proved effective in identifying genes responsible for extreme forms of early-onset disease segregating as single-gene (mendelian) disorders. Genes underlying several distinct, familial forms of nonautoimmune diabetes — including maturity-onset diabetes of the young, mitochondrial diabetes with deafness, and neonatal diabetes — were characterized (see the review by Waterfield and Gloyn[3]). Similar approaches revealed mutations in genes responsible for rare forms of severe childhood obesity, including the genes encoding leptin, the leptin receptor, and proopiomelanocortin (see the review by O'Rahilly[4]). These discoveries have provided insights into processes critical for the maintenance of normal glucose homeostasis and energy balance and clues to the inner workings of the pancreatic beta cell and hypothalamus. For many families, this information has led to improved diagnostic and therapeutic options (described in more detail below).

Attempts to apply similar approaches to families in which either common forms of diabetes or obesity is segregating have proved to be largely unrewarding,[5] and the second wave of discovery involved a switch to tests of association. Although intrinsically more powerful than linkage analysis, association analysis suffers from the disadvantage that the signal can be detected only if one examines

Figure 1. Genomic Locations of Proven Signals of Nonautoimmune Forms of Diabetes.

Signals are shown according to their location on each chromosome. Genes causing monogenic and selected syndromic forms of diabetes are shown to the left: genes implicated in maturity-onset diabetes of the young (red triangles) and those representing loci causal for other monogenic and syndromic forms of diabetes (green triangles). Common variants that have significant genomewide associations with multifactorial forms of diabetes are shown to the right (blue triangles); for these variants, the genes named within the triangles are indicative of signal position, but in most instances, formal proof that these are the specific genes responsible for the association is lacking.

the causal variant itself or a nearby marker with which it is tightly correlated. Until the advent of methods that enabled genomewide surveys of association, researchers were therefore obliged to direct their attention to specific candidate variants or genes of interest.[6] In retrospect, it is obvious that most such studies were seriously underpowered or focused on inappropriate candidates.[6] Nevertheless, by accruing data over the course of multiple studies, some genuine susceptibility variants were identified. Common coding variants in *PPARG* and *KCNJ11* (each of which encodes a protein that acts as a target for classes of therapeutic agents widely used in diabetes management) were shown to have modest effects on the risk of type 2 diabetes.[7,8] Resequencing of the gene encoding the melanocortin-4 receptor (MC4R) resulted in the identification of low-frequency coding variants that explain approximately 2 to 3% of cases of severe obesity.[9]

The third, and most successful, wave of discovery has been driven by systematic, large-scale surveys of association between common DNA sequence variants and disease. The first demonstration that unbiased discovery efforts could reveal new insights into the pathogenesis of type 2 diabetes resulted from identification of the association between type 2 diabetes and variants within *TCF7L2* (encoding transcription factor 7–like 2, a protein not previously identified as a biologic candidate).[10] *TCF7L2* has now been shown to modulate pancreatic islet function.[11]

The number of loci for which there is convincing evidence that they confer susceptibility to type 2 diabetes started to grow in early 2007 with the publication of the first genomewide as-

Figure 2. Genomic Locations of Proven Signals of Body-Mass Index (BMI), Obesity, and Related Phenotypes.

Signals are shown according to their location on each chromosome. Genes causing monogenic and selected syndromic forms of obesity (red triangles) are shown to the left. Common variants that have significant genomewide associations with BMI or multifactorial obesity are shown to the right: loci implicated in BMI or weight variation at the population level (solid blue triangles), additional loci identified in case–control analyses of extreme obesity (open blue triangles), and variants identified primarily because of their association with waist circumference or waist-to-hip ratio (solid green triangles). For the variants shown to the right, the genes named within the triangles are indicative of signal position, but in most instances, formal proof that these are the specific genes responsible for the association is lacking.

sociation studies.[12-18] Together, these studies revealed six new associations, including variants near *CDKAL1*, *CDKN2A*, and *CDKN2B* (which encode putative or known regulators of cyclin-dependent kinases) and *HHEX* (which is transcribed into a homeobox protein implicated in beta-cell development). Typically each copy of a susceptibility allele at one of these loci is associated with a 15 to 20% increase in the risk of diabetes. Since then, the dominant approach to discovery has involved ever-larger aggregations of genomewide association data from multiple samples so as to improve the power to identify variants of modest effect: these studies have revealed more than 20 additional confirmed signals of susceptibility to type 2 diabetes[19-22] (Table 1 and Fig. 1). Though early studies were restricted to samples obtained from persons of European descent, genomewide association analyses conducted in other ethnic groups are now emerging.[23,24,29] The current total of approximately 40 confirmed type 2 diabetes loci includes variants in or near *WFS1* (wolframin) and the hepatocyte nuclear factors *HNF1A* and *HNF1B* (genes that also harbor rare mutations responsible for monogenic forms of diabetes)[30-33]; the melatonin-receptor gene *MTNR1B* (which highlights the link between circadian and metabolic regulation)[26-28]; and *IRS1* (encoding insulin-receptor substrate 1), one of a limited number of type 2 diabetes loci with a primary effect on insulin action rather than on secretion.[25]

Glossary

Allele: One of two or more versions of a genetic sequence at a particular location in the genome.

Association analysis: An approach to susceptibility-gene discovery that relies on identifying genetic variants whose allele frequencies are robustly correlated with either disease status or the level of a trait of interest.

Candidate-gene study: An approach to susceptibility-variant discovery that focuses on genetic analysis restricted to one or more candidate genes — genes that have typically been selected on the basis of a perceived match between their known or presumed functions and the biologic characteristics of the disease in question.

Coding variant: The part of the genomic DNA sequence that encodes proteins (consisting of approximately 1.5% of the total human genome).

Genomewide association study: An approach used in genetics research to look for associations between many (typically hundreds of thousands) of specific genetic variations (most commonly, single-nucleotide polymorphisms) and particular diseases or traits.

Homozygous: Having the same allele on both chromosomes at a particular location in the genome.

Linkage analysis: An approach to susceptibility-gene discovery that relies on matching family-level patterns of segregation of the disease of interest with genetic markers of known location.

Monogenic disease: Genetic disease attributable to variants with large effects on disease status. Because of the high penetrance of such variants, the disease typically cosegregates in a classic mendelian fashion (e.g., dominant or recessive).

Next-generation sequencing: DNA sequencing that harnesses advances in miniaturization technology to simultaneously sequence multiple areas of the genome rapidly and at low cost.

Noncoding variant: A DNA sequence variant that is located outside the coding sequence; some are likely to be involved in gene regulation.

Syndromic disease: Syndromes are characterized by the concomitant occurrence of several distinct clinical features. In syndromic forms of diabetes such as Wolfram's syndrome, a rare mutation of large effect leads not only to diabetes but also to a diversity of other features including optic atrophy and deafness.

Transcript: An RNA sequence resulting from transcription of a DNA sequence (often a gene).

obesity have been similarly productive, with three main strategies being adopted (Table 2 and Fig. 2). Genomewide association studies of population-based samples to examine the full range of BMI values have identified approximately 30 loci influencing BMI and the risk of obesity. The strongest signal remains the association with variants within *FTO* (the fat-mass and obesity–related gene).[13,34,45] Other signals near *BDNF*, *SH2B1*, and *NEGR1* (all implicated in aspects of neuronal function) reinforce the view of obesity as a disorder of hypothalamic function.[35,37,38,43] A second approach, focusing on case–control analysis of persons selected from the extremes of the BMI distribution, has delivered a complementary, only partly overlapping, set of loci.[39,42,46,47] Finally, genomewide analyses of patterns of fat distribution, prompted by the particularly deleterious health effects of visceral fat accumulation, have characterized approximately 15 loci that are largely distinct from those influencing overall adiposity[36,40,41,44]: many of the 15 display markedly stronger associations in women than in men.

FROM GENES TO CLINICAL PRACTICE

Despite the growing number of loci discovered, the contribution of genetic discoveries to the clinical management of diabetes and obesity remains limited to the small proportion of cases with monogenic forms of disease. What, then, are the obstacles impeding the clinical translation of the scores of multifactorial variants now defined?

The first is the modest effect size of the implicated variants. The common variants with the greatest effects on the risk of type 2 diabetes (*TCF7L2* in Europeans, *KCNQ1* in Asians) result in lifetime prevalence rates that are, in persons carrying two copies of the risk allele, roughly double those seen in persons with none.[10,23,24] The association signal at *FTO* accounts for less than 0.5% of the overall variance in BMI, equivalent to a difference of 2 to 3 kg between adults homozygous for the risk allele and those homozygous for the alternative allele.[13] Most other variants associated with type 2 diabetes and BMI have effects considerably smaller than these. More detailed analysis of the associated regions may reveal that some of these associations are driven by causal variants with larger effects, although empirical evidence supporting this assertion is limited.[22] In contrast, the mutations underlying monogenic forms of diabetes and obesity have far more dramatic clinical consequences: in pedigrees segregating these conditions, knowing whether a family member has inherited a given causal allele generally allows for the confident prediction of disease status.

A second obstacle to the translation of variants implicated in multifactorial forms of diabetes and obesity relates to the speed with which risk-allele discovery has led to an improved understanding of the biologic basis of disease. Most alleles implicated in monogenic and syndromic forms of diabetes and obesity alter the coding sequence and therefore have dramatic

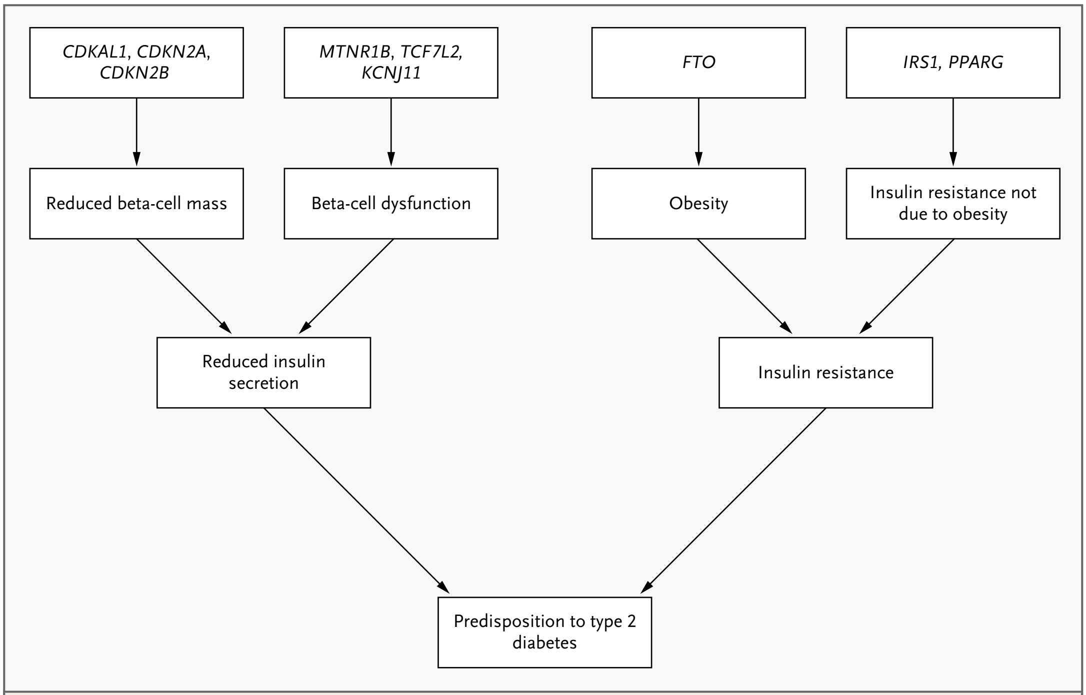

Figure 3. Pathways to Type 2 Diabetes Implicated by Identified Common Variant Associations.

Type 2 diabetes results when pancreatic beta cells are unable to secrete sufficient insulin to maintain normoglycemia, typically in the context of increasing peripheral insulin resistance. The beta-cell abnormalities fundamental to type 2 diabetes are thought to include both reduced beta-cell mass and disruptions of beta-cell function. Insulin resistance can be the consequence of obesity or of obesity-independent abnormalities in the responses of muscle, fat, or liver to insulin. Examples of susceptibility variants that, given current evidence, are likely to influence predisposition to type 2 diabetes by means of each of these mechanisms are shown.

and largely predictable effects on the function of the gene. The use of molecular diagnostics to derive clinically useful prognostic and therapeutic information relies on this relatively straightforward assignment of functional significance. In multifactorial disease, however, most susceptibility variants lie outside the coding regions of genes and are assumed to influence transcript regulation rather than gene function.

Characterization of the downstream consequences of these “noncoding” variants is difficult, given our rudimentary knowledge of the mechanics of gene regulation. Detailed functional studies are required to translate these genomic “signposts” into biologic knowledge that can spur translational development, and there have been relatively few successes.[48] Indeed, at most susceptibility loci, it remains far from clear even which transcripts mediate the susceptibility effects that have been observed.

The time required to achieve clinical translation is often underestimated,[49] and most of the discoveries in multifactorial disease have simply been too recent for their full translational potential to be realized. That potential lies in three main areas: the characterization of disease mechanisms that provide new targets for treatment and prevention, improved risk prediction and differential diagnosis, and personalized treatment and prevention.

FROM GENETICS TO BIOLOGY

An improved understanding of pathophysiology achieved through genetic discovery provides new opportunities for treatment, diagnosis, and monitoring. Studies of risk variants for type 2 diabetes in healthy populations have shown that most variants act through perturbation of insulin secretion rather than insulin action, establishing inherited abnormalities of beta-cell function or mass (or both) as critical components of the progression to type 2 diabetes (Fig. 3).[22,50] (An interactive graphic depicting proposed mechanisms of

An interactive graphic is available at NEJM.org

some susceptibility variants associated with type 2 diabetes is available at NEJM.org.) At loci for which there is evidence of a primary effect driven by abnormalities of insulin action, both obesity-dependent and obesity-independent mechanisms are involved (Fig. 3).[22] As described above, it is not always easy to link association signals to specific transcripts, but some of the genes more confidently assigned to type 2 diabetes susceptibility — *TCF7L2*, *SLC30A8*, and *CDKN2A* and *CDKN2B* — relate to Wnt signaling, zinc transport, and cell-cycle regulation, respectively, suggesting that these functions have roles in the maintenance of normal islet function.[22,51] Beyond that, efforts to identify key processes in the pathogenesis of type 2 diabetes — for example, by showing that genes encoding members of particular pathways are overrepresented at susceptibility loci — have not been particularly rewarding.[22] Either type 2 diabetes is highly heterogeneous, or those fundamental disease processes are poorly captured by existing biologic knowledge.

Efforts to achieve therapeutic modification of weight have had little success. The identification of new pathways amenable to safe and effective weight manipulation would be a valuable "deliverable" from genetic-discovery efforts. However, the transition from association signal to causal mechanism has not been straightforward, especially when the disease involves tissues as inaccessible to direct study as the human hypothalamus. Consider the example of *FTO*.[13] Although the association signal maps to a clearly defined region of the gene, and the effect is comparatively large, there is still some doubt as to whether *FTO* itself is responsible for the weight phenotype, rather than one of the nearby genes such as *RPGRIP1L* (also expressed in the hypothalamus, with responses to alterations in nutritional and hormonal status similar to those of *FTO*[52]). Studies of mice with disruptions of *Fto* sequence[53,54] are consistent with the hypothesis that *FTO* mediates the BMI effect in humans, whereas studies of human *FTO* mutations have been less clear-cut.[55,56] Notwithstanding these data, the story emerging from the growing number of loci supports the view of overall obesity as a disease of hypothalamic dysregulation.[37,43] In contrast, variation in patterns of fat distribution is associated with variants within genes that influence adipocyte development and function.[40,41,44] How best to use this information to effect early translation into new therapeutic or preventive approaches remains uncertain.

One characteristic of metabolic disease is the cluster of traits referred to as the metabolic syndrome. However, the genetic evidence to date provides limited support for the metabolic syndrome as a defined pathophysiological entity, perhaps indicating that this clustering is driven by environmental factors. Though BMI-associated variants such as *FTO* modulate the risk of type 2 diabetes and hyperlipidemia,[57] and loci altering lipid levels have secondary effects on the risk of coronary artery disease,[58,59] there is little suggestion that the variants implicated in individual components of the metabolic syndrome overlap. At some loci, the patterns of association actually run counter to the broader correlative patterns of the metabolic syndrome. At the glucokinase regulator gene *GCKR*, for example, one common variant allele increases triglyceride levels yet lowers glucose levels.[15,60,61] The complexity of the relations that can exist at the genetic level between closely related phenotypes is further illustrated by the observation that alleles associated with similar degrees of fasting hyperglycemia in healthy populations have highly variable effects on the risk of type 2 diabetes later in life.[20]

PREDICTION AND DIFFERENTIAL DIAGNOSTICS

In cases of monogenic disease, genetic information can provide powerful diagnostic and predictive value for selected patients. Since subtypes of monogenic diabetes and obesity vary in their prognostic implications and therapeutic recommendations, a definitive molecular diagnosis is an important component of clinical management (Table 3).[3,62] To date, the use of molecular diagnostic tools has been limited by the expense of using conventional sequencing technologies to screen known causal genes for mutations that are often specific to a given family. Next-generation sequencing technologies are likely to be transformative in the medium term, though distinguishing pathogenic mutation from incidental variation will remain a challenge. In the meantime, improved biomarkers of diabetes subtypes that enable the more precise targeting of diagnostic resequencing would be valuable. For ex-

Table 3. Initial Treatments for Various Diabetes Subtypes.*

Diabetes Subtype	Causal Genes	Optimal Treatment
Type 1 diabetes	About 40 known (genes in HLA region, *INS, PTPN22,* and others)	Lifelong insulin
Type 2 diabetes	About 40 known (*TCF7L2, CDKAL1,* and others)	Metformin as primary treatment; also sulfonylureas, glitazones, or insulin
LADA	Genes in HLA region, *INS,* and *PTPN22* (as in type 1 diabetes)	Early recourse to insulin therapy
GCK-MODY	*GCK*	Diet modification
HNF1A MODY	*HNF1A*	Sulfonylureas (low dose)
Mitochondrial diabetes	*MTTL1*	Early recourse to insulin therapy
Lipodystrophies	*LMNA, PPARG, AGPAT2, CAV1, BSCL2, LMNB2,* and *AKT2*	Uncertain; thiazolidinediones for some subtypes
Neonatal diabetes	*KCNJ11, ABCC8*	Sulfonylureas (high dose)
Neonatal diabetes	*INS*	Insulin

* GCK denotes glucokinase, LADA latent autoimmune diabetes in adults, MODY maturity-onset diabetes of the young, and tRNA transfer RNA.

ample, patients with maturity-onset diabetes of the young caused by *HNF1A* mutations have recently been shown to have C-reactive protein (CRP) levels well below those of patients with other subtypes of diabetes, suggesting that CRP could form the basis of a useful diagnostic test.[63] This observation also exemplifies the early translation of genetic discoveries, since it came directly from genomewide association studies showing that CRP levels are influenced by common variants near *HNF1A*.

The effect sizes of the known, common variants influencing the risk of type 2 diabetes and variation in adult BMI are modest, and the proportion of overall predisposition explained is small: approximately 5 to 10% for type 2 diabetes and 1% for BMI.[22,43] As a result, the ability to perform individual-level prediction with respect to these traits is limited. By combining data from multiple loci, one can identify persons who have inherited especially high or low numbers of risk alleles: the risk of type 2 diabetes differs by a factor of approximately 4 between persons in the top 1% and those in the bottom 1% of the "risk-score" distribution.[64-67] However, the risk profiles of many such persons are already discernible on the basis of conventional risk factors (e.g., BMI or family history), and there is limited evidence to suggest that information about genetic predisposition can be used effectively to guide the modification of long-term behavior. The discriminative accuracy of genetic profiling of known type 2 diabetes risk variants (as measured by means of receiver-operating-characteristic curves) is only approximately 60%,[64-67] well below the threshold required for clinical usefulness and the degree of prediction achievable on the basis of nongenetic risk factors.[68] Furthermore, estimates of risk can depend crucially on exactly which variants are included in the risk profile.[69] The key to improved performance will be the identification of risk variants with greater effect sizes than those discovered so far. Since existing genomewide association studies have most likely captured any common variants of large effect, the search is now focused on less-common variants.

A person's risk of type 2 diabetes or obesity reflects the joint effects of genetic predisposition and relevant environmental exposures. Efforts to determine whether these genetic and environmental components of risk interact (in the statistical sense that joint effects cannot be predicted from main effects alone)[70] face challenges associated with measuring relevant exposures (diet and physical activity being notoriously difficult to estimate) and the effect of imprecision on statistical power.[71] Although claims that statistical interactions reflect shared mechanisms (i.e., that the interacting factors act

The New England Journal of Medicine

Copyright © 2010 Massachusetts Medical Society. All rights reserved.

through the same pathways) are probably overstated, understanding the relative contributions of genetic and environmental components to risk is important. After all, environmental factors can be modified more readily than genetic factors.

Genetic discoveries have provided a molecular basis for the clinically useful classification of monogenic forms of diabetes and obesity.[3,4] Will the same be true for the common forms of these conditions? Probably not: as far as the common variants are concerned, each patient with diabetes or obesity has an individual "barcode" of susceptibility alleles and protective alleles across many loci. It is possible to show that the genetic profiles of lean subjects with type 2 diabetes and obese subjects with type 2 diabetes are not identical, but these differences appear to be inadequate for clinically useful subclassification.[22,72] If efforts to uncover less prevalent, higher-penetrance alleles are successful, more precise classification of disease subtypes may become possible, particularly if genetic data can be integrated with clinical and biochemical information. For example, in persons presenting with diabetes in early adulthood, there are several possible diagnoses: various subtypes of maturity-onset diabetes of the young or mitochondrial diabetes, for example, as well as type 1 or type 2 diabetes. Assigning the correct diagnosis has both prognostic and therapeutic benefits for the patient (Table 3).

TARGETED TREATMENT AND PREVENTION

Recommended therapies for the various subtypes of diabetes differ (Table 3).[3,4,62,73-75] In monogenic forms of diabetes, at least, genetic testing already drives the choice of therapy. For example, in patients who have maturity-onset diabetes of the young due to mutations in the gene encoding glucokinase (GCK), the hyperglycemia is mild and stable, the risk of complications is low, and dietary management is often sufficient. In contrast, in patients who have maturity-onset diabetes of the young due to mutations in *HNF1A*, the disease follows a more aggressive course, with a greater risk of severe complications, but is particularly responsive to the hypoglycemic effects of sulfonylureas.[62,73] Most children with neonatal diabetes have mutations in *KCNJ11* or *ABCC8*, adjacent genes that jointly encode the beta-cell ATP-sensitive potassium channel that mediates glucose-stimulated insulin secretion and is the target of sulfonylureas. In such children, treatment with sulfonylureas has proved more effective and convenient than the lifelong insulin therapy previously considered the default option.[74,75] In children with severe obesity due to profound leptin deficiency, exogenous leptin therapy is lifesaving.[76]

As yet, there are insufficient genetic data to support management decisions for common forms of type 2 diabetes and obesity.[77] Although the *TCF7L2* genotype is associated with variation in the response to sulfonylurea treatment,[78] the effect is too modest to guide the care of individual patients. For the time being, the contribution of genetic information to therapy is most likely to come through the drug-discovery pipeline. Information from genetic studies could be used to identify new targets for pharmaceutical intervention that have validated effects on physiological characteristics, to provide information about new and existing targets (e.g., clues about the long-term safety of pathway intervention),[32] and to characterize high-risk groups to enable more efficient clinical trials of agents designed to reduce the progression of type 2 diabetes or obesity or the risk of complications.

SUMMARY

Given the substantial time it takes to translate basic biomedical discoveries into clinical tools,[49] any current assessment of the clinical value of recent advances in the genetic basis of common diseases is probably an underestimate. An improved understanding of fundamental disease mechanisms is already emerging; this will underpin future therapeutic advances. But the expansion of personalized medicine beyond monogenic forms of disease awaits a more complete description of predisposition. The boundaries of personalized medicine will be much clearer in a few years, after large-scale genomewide resequencing efforts (now under way) provide a systematic, comprehensive description of the relations between genome sequence variation and major clinical phenotypes.

An interactive timeline is available at NEJM.org

CARDIOVASCULAR DISEASE IS THE LEADING CAUSE OF DEATH IN THE UNITED States. Considerable progress has been made in the past 50 years to define, identify, and modify risk factors for cardiovascular disease (e.g., hypertension, dyslipidemia, obesity, type 2 diabetes, cigarette smoking, and physical inactivity) and to develop treatments, such as coronary care units, percutaneous coronary interventions, and beta-blockers. These efforts have resulted in an age-adjusted decline in cardiovascular mortality.[1] In addition, it is now possible to detect subclinical disease by means of blood biomarker testing[2] or imaging measurements[3] years before the onset of symptoms or other clinical manifestations.[4] Despite this progress, mechanisms that underlie individual differences in the presentation and pathophysiological features of cardiovascular disease are poorly understood. In this article, we review genetic and genomic studies in cardiovascular medicine that have helped to elucidate some of these mechanisms during the past decade (Fig. 1, and interactive timeline, available with the full text of this article at NEJM.org).

MENDELIAN AND CANDIDATE-GENE STUDIES

Ten years ago, the draft sequence of the human genome, which was produced by scientists working on the Human Genome Project[5] and others,[6] was first described, leading to an expansion in the understanding of genetic contributions to cardiovascular disease. Before the Human Genome Project, many genes associated with mendelian cardiovascular disease had been identified.[7] These forms of cardiovascular disease are rare and constitute a minority of clinical cardiovascular diseases. Genetically, they are simple in that a mutation in a single gene is sufficient to cause disease, so mendelian disease is said to be monogenic. Examples include forms of premature myocardial infarction, dilated and hypertrophic cardiomyopathy, heart failure, arrhythmogenic right ventricular dysplasia, the long-QT syndrome, and aortic aneurysms.[7] Recessive mutations underlie familial forms of cardiovascular risk factors, such as hypertension, hypercholesterolemia, and type 2 diabetes. Knowledge obtained through the identification of genes associated with mendelian disease has led to breakthrough discoveries in mechanisms of cardiovascular disease and its treatment. A compelling illustration is the Nobel-Prize–winning discovery that mutations affecting the low-density lipoprotein (LDL) receptor cause hypercholesterolemia and early-onset myocardial infarction, which led to LDL cholesterol–lowering therapies that reduce the risk of cardiovascular events.[8]

GENOMICS OF CARDIOVASCULAR RISK AND DISEASE

ROLE OF GENOMEWIDE ASSOCIATION STUDIES

The large majority of cardiovascular diseases, however, are polygenic, with both heritable and environmental contributions.[9] Moreover, there are heritable, polygenic com-

1973–1975 Mutations affecting the LDL receptor reported to cause familial hypercholesterolemia

1975 DNA sequencing described by Sanger et al. and by Maxam and Gilbert

1977 Discovery of introns

Development of electrophoretic methods for DNA sequencing

1981–1982 First reports of transgenic mice and flies

1983 First disease gene mapped, for Huntington's disease

Polymerase chain reaction (PCR) invented

1986 First disease gene (*DMD*, mutation of which causes Duchenne's muscular dystrophy) discovered by positional cloning

First human genetic map obtained (using restriction-enzyme digestion) **1987**

1989 Microsatellites used as genetic markers

1990 Launch of Human Genome Project

Mutation in a "sarcomere" gene (encoding myosin heavy chain) implicated in familial hypertrophic cardiomyopathy

Expressed sequence tags (ESTs) used to describe fragments of genes **1991**

Genetic variants in genes encoding proteins in the renin–angiotensin system associated with familial hypertension

Second-generation human genetic map using microsatellite genetic markers **1992**

Mutant dystrophin implicated in dilated cardiomyopathy **1993**

Mutations in factor V ("Leiden") gene associated with resistance to protein C **1994**

1995 Discovery of several canonical Romano–Ward susceptibility genes for the long-QT syndrome (LQTS)

Genetic variants affecting renal sodium channels associated with familial forms of hypertension

Mouse genetic map completed **1996**

1997 Discovery of genetic variants causing susceptibility to Jervell and Lange-Nielsen LQTS

2001 Initial sequencing and analysis of the human genome publicly reported

Over past decade, mutations in multiple sarcomere genes implicated in cardiac hypertrophy in the general population

Discovery of haplotype structure of human genome

Development of genotype arrays, including SNP chips

Sequence of the human genome described **2003**

Report of risk stratification using genotyping of LQTS variants

Development of in situ sequencing **2005**

Mutations in genes affecting glycogen-storage disease genes shown to cause hypertrophic cardiomyopathy

Detailed map of single-nucleotide variants reported by the International HapMap Project

First report of a gene associated with a cardiovascular trait using GWAS: *NOS1AP* associated with prolonged QT interval **2006**

Variants in genes encoding sarcomere proteins and affecting metabolism implicated in cardiac hypertrophy

Mutations in *PCSK9* implicated in lower levels of LDL and lower risk of coronary heart disease

2007 Reports of *TCF7L2* and multiple other novel gene loci associated with type 1 and type 2 diabetes mellitus using GWAS

GWAS uncover variants in *FTO* associated with body-mass index and obesity.

Two reports of SNPs at 9p21 associated with myocardial infarction and related forms of coronary artery disease (revealed by GWAS)

Wellcome Trust Case Control Consortium reports associations using GWAS of gene variants with seven conditions including type 1 and type 2 diabetes mellitus and coronary artery disease.

GWAS reveals association between gene variants on chromosome 4q25 and atrial fibrillation.

Phenotype and genotype GWAS data, including those from the Framingham Heart Study, made available in the NIH Database of Genotype and Phenotype (dbGaP)

Phenotype and genotype GWAS data made available in the NIH dbGaP for the MultiEthnic Study of Atherosclerosis and the Women's Health Initiative

2008 Reports of multiple gene loci associated with lipid traits and with body-mass index using GWAS

Reports of loci associated with intracranial aneurysm

Reports of cardiovascular pharmacogenetic effects (prolonged QT interval, increased warfarin maintenance dose, statin-induced myopathy) using GWAS

NHLBI begins whole-exome and whole-genome sequencing of the Framingham Heart Study and other cohorts for studying cardiovascular disease. **2009**

GWAS implicate genetic variants in early-onset myocardial infarction, QT-interval prolongation, blood pressure and hypertension, echocardiographic measures of cardiac structure, and blood-cell traits.

Exome sequencing identifies mutations in *SLC26A3* for renal salt wasting in Bartter's syndrome.

2010 Large GWAS for CVD risk factors report total of 95 gene loci associated with lipid traits, >30 gene loci associated with type 2 diabetes mellitus, >30 gene loci associated with body-mass index and obesity, and hundreds of variants associated with height.

GWAS uncover gene loci associated with cigarette-smoking behavior, sudden cardiac death and ventricular fibrillation, thrombosis factors and platelet function, and ECG interval (RR, PR, QRS).

Variants in 9p21 are found to be associated with abdominal aortic aneurysm.

Exome sequencing identifies *ANGPTL3* mutations in familial combined hypolipidemia.

Whole-genome sequencing identifies *ABCG5* mutations in severe hypercholesterolemia.

Initial report of genomewide sequencing of multiple persons in the 1000 Genomes project

Large GWAS yields >30 gene loci associated with clinical coronary artery disease. **2011**

Large GWAS reports >30 gene loci associated with blood pressure and hypertension.

GWAS also yield variants in *MYH6* associated with sick sinus syndrome and variants associated with dilated cardiomyopath and carotid intima–media thickness.

ponents of cardiovascular risk factors and subclinical disease, including coronary artery disease.[10] Approaches to identifying the genetic causes of polygenic cardiovascular diseases (and other polygenic diseases) before completion of the draft sequence of the human genome were largely unsuccessful. A decade later, hundreds of loci associated with many cardiovascular diseases and traits have been identified. This genetic bounty is the yield of genomewide association studies, which involve testing of a large set of genetic variants in case and control subjects from a population to determine which variants are associated with the disease in question (see the Glossary).[11]

The common disease–common variant hypothesis proposes that common variants, which are defined as variants with a prevalence of at least 5% in the population, have a role in the cause and

Glossary

Allele: One of two or more copies of a genetic sequence at a chromosomal location. Alleles can be considered according to their frequencies in the human population, ranging from common variants (minor allele frequency, >5%) to low-frequency variants (minor allele frequency, 0.5 to 5%) to rare or private alleles in one or a limited number of families (minor allele frequency, <0.5%). A null allele is not functional.

Candidate-gene study: An approach used in genetics research that focuses on suspected, or candidate, genes that have been selected because of a perceived match between their known or presumed function and biologic function in the disease under investigation.

Exome: All known protein-coding sequences, or exons, in the human genome, constituting approximately 1 to 2% of the 3.2 billion nucleotide base pairs in the human genome.

Gene enhancer: A short region of DNA that can be bound with proteins, such as trans-acting factors (i.e., factors acting from a different molecule), to enhance transcription levels of genes in a gene cluster. Although enhancers are usually cis-acting (i.e., acting from the same molecule), an enhancer does not need to be close to the genes it acts on and may not be located on the same chromosome.

Genomewide association study: An approach used in genetics research to look for associations between many (typically hundreds of thousands) specific genetic variations (most commonly single-nucleotide polymorphisms) and particular diseases.

Genotyping array: A technique used to study many genes at once. Thousands of gene sequences are placed in known locations on a glass slide. A sample containing DNA or RNA is deposited on the slide, or gene chip. The binding of complementary base pairs from the sample and the gene sequences on the chip can be measured with the use of fluorescence to detect the presence and determine the amount of specific sequences in the sample.

Induced pluripotent stem cell: A type of pluripotent stem cell derived from a nonpluripotent cell, typically an adult somatic cell such as a fibroblast, by transfection of a stem-cell–associated gene.

Haplotype maps: Maps of a set of DNA variations, or polymorphisms, that tend to be inherited together. Haplotype maps are used to aid gene-discovery efforts.

Haplotype structure: Patterns of haplotypes that define the structure of regions of the genome. Haplotype structure is used to compare genome regions across populations or species.

Locus: The specific chromosomal location of a gene or other DNA sequence of interest.

Mendelian inheritance: Patterns of inheritance characteristic of organisms that reproduce sexually, as described by Austrian monk Gregor Mendel in the mid-19th century.

Mendelian randomization: A method that uses measured variation in genes of known function to examine the causal effect of a modifiable exposure on a disease. It provides unbiased estimates of the effects of a putative casual variable without the need for a traditional randomized trial.

Next-generation sequencing: DNA sequencing that harnesses advances in miniaturization technology to simultaneously sequence multiple areas of the genome rapidly and at low cost.

Noncoding DNA sequence: A DNA sequence that does not encode proteins. Noncoding DNA sequences, once referred to as "junk DNA," account for the majority of genome sequences and are now known to harbor regions that regulate gene expression.

Polygenic: Produced by two or more genes.

Single-nucleotide polymorphism: A single-nucleotide variation in a genetic sequence; a common form of variation in the human genome.

Splice variants: Abnormal variations in RNA splicing that are implicated in a disease. Many genetic disorders result from splicing variants.

Whole-exome sequencing: Sequencing of the coding regions, or exons, of an entire genome.

Figure 2. Genomic Locations of Genetic Variants Associated with the Risk of Myocardial Infarction and Heart Failure.

Genetic variants that are associated with myocardial infarction (blue) and heart failure (orange) are shown according to their chromosomal location. LOC denotes locus.

pathophysiology of common diseases. It is on this premise that the genomewide association study is based, since it comprises tests of association between disease and common variants spread throughout the genome. On the basis of this approach, researchers have assembled catalogues of cardiovascular variants, using genotyping arrays, haplotype maps, and statistical methods. Changes in data-sharing policies have led to the creation of publicly available genome databases. International collaborations combining study cohorts, often including tens of thousands of research participants, have been formed.[12]

The astonishingly large number of new loci associated with cardiovascular risk factors, subclinical indexes, and disease end points have provided insights into the biologic pathways that underlie disease (Fig. 2). The application of such findings to the prediction of risk and to the prevention and treatment of disease is premature and awaits considerable research.

CORONARY ARTERY DISEASE AND MYOCARDIAL INFARCTION

Genomewide association studies have identified about 30 loci associated with myocardial infarction and coronary artery disease (Table 1).[13-35] A meta-analysis of 14 such studies that involved 22,233 case subjects with coronary artery disease and 64,762 control subjects of European descent and that were followed by replication studies involving 56,682 case and control subjects identified 13 new loci associated with coronary artery disease, in addition to confirming 10 of 12 previously reported loci.[14] *ABO* and *ADAMTS7* were found to be associated with angiographically confirmed coronary atherosclerosis, *CNNM2* with high blood pressure, and the *APOA5* gene cluster with elevated levels of triglycerides and cholesterol subfractions. The majority of loci associated with myocardial infarction reside in genomic regions that have not previously been implicated in coronary artery disease; only a minority of loci mediate an

effect through known risk factors. A second meta-analysis of genomewide association studies involving more than 30,000 case and control subjects showed an additional four new loci associated with coronary artery disease in multiple ethnic groups.[15]

Studies of early-onset myocardial infarction have identified more than 10 risk loci.[13] The most strongly associated locus is 9p21.[36,37] This region harbors genes (*CDKN2A* and *CDKN2B*) that are implicated in cell cycling and cancer, although the single-nucleotide polymorphisms (SNPs) associated with myocardial infarction are located not near these or other protein-coding genes but rather within a noncoding RNA molecule called ANRIL (for antisense noncoding RNA in the *INK4* locus). The expression of ANRIL splice variants, but not *CDKN2B* or other nearby genes, is associated with atherosclerosis.[38] SNPs at the 9p21 locus are also associated with other cardiovascular diseases, including stroke[39] and aortic aneurysm.[40]

Loci associated with coronary artery disease harbor genes known to be important in lipid variation, including *SORT1*, *PCSK9*, *HNF1A*, *MRAS*, and *LPA*. The position of other SNPs implicates inflam-

matory processes in conferring a risk of coronary atherosclerosis.

HEART FAILURE

Genomewide association studies have identified many possible loci associated with heart failure and death from heart failure, although few of such studies have been replicated.[16,17] Genomewide association studies for heart failure have been limited by modest numbers of cases of heart failure (relative to the number of such studies for coronary artery disease) and the heterogeneous nature (and thus heterogeneic sets of cases) of heart failure. A recent genomewide association study for idiopathic dilated cardiomyopathy identified variants in *HSPB7*, encoding a heat-shock protein previously implicated in heart failure, and *BAG3*; a marked myopathy develops in mice deficient in *Bag3*.[18]

ARRHYTHMIAS

Genomewide association studies have uncovered genetic variants for arrhythmias, including atrial fibrillation,[28-30] ventricular fibrillation,[32] sudden cardiac death,[33,34] and the sick sinus syndrome[31] (Table 1). *MYH6*, a previously unidentified gene associated with susceptibility to the sick sinus syndrome, encodes the alpha heavy-chain subunit of cardiac myosin,[31] suggesting that myosin proteins may regulate cardiac conduction in addition to myocyte function.

PERIPHERAL AND CEREBRAL VASCULAR DISEASES

Genomewide association studies have yielded evidence of varying strength for genetic loci associated with ischemic stroke,[19,20] intracranial aneurysm,[21-23] peripheral arterial disease,[24,25] aortic aneurysm,[25-27] venous thromboembolism,[35] and erythrocyte phenotypes[41] (Table 1). In some cases, these loci are common to coronary artery disease and myocardial infarction, suggesting a common genetic contribution to multiple vascular beds.

MODIFIABLE RISK FACTORS AND SUBCLINICAL DISEASE

Genome consortia with sample sizes exceeding 10,000 cases have investigated major modifiable risk factors (e.g., hypertension, dyslipidemia, type 2 diabetes, and cigarette smoking) and obesity, using quantitative measures and clinically relevant extreme end points (Table 2). These studies point to loci associated with hypertension (as defined by the use of antihypertensive therapy or elevations in blood pressure),[42] LDL and high-density lipoprotein (HDL) cholesterol and triglycerides,[43] the number of cigarettes smoked,[44] type 2 diabetes (with the use of quantitative traits of fasting glucose and glycated hemoglobin levels),[45,46] and obesity (with the use of body-mass index and adiposity-related traits).[47,48] Studies have also identified multiple loci associated with other presumed quantitative biomarkers of cardiovascular risk and presymptomatic coronary artery disease (e.g., fibrinogen,[49] C-reactive protein,[50] intercellular adhesion molecule 1,[51] plasma homocysteine,[52] and carotid-artery intima–media thickness and plaque[53]).

Newer approaches for establishing evidence of causality use human populations as a model system. Mendelian randomization analysis takes advantage of the lifelong association between a risk allele and a quantitative measure of a biomarker for clinical coronary artery disease to estimate whether there is evidence of a causal association between the biomarker and the disease. Mendelian randomization studies have used genetic variants that have previously been implicated by genomewide association studies to provide evidence for a causal association between LDL cholesterol (variants in *LDLR*)[54] or lipoprotein(a) (variants in *LPA*)[55] and coronary artery disease and evidence against a causal association between C-reactive protein (variants in *CRP*) and coronary artery disease.[56]

Current genomewide association studies focus on large populations in order to strengthen the evidence for association and replication. For example, a genomewide association study of more than 100,000 research participants identified 95 loci associated with at least one of three lipids: LDL and HDL cholesterol and triglycerides.[43] Although each individual variant had only a modest effect, the combined effect of the 95 loci explained approximately 25% of the genetic variance in LDL and HDL cholesterol levels. Similarly, large meta-analyses of variants that are associated with type 2 diabetes[45] and myocardial infarction[14] suggest that these variants, in aggregate, account for 25% and 10%, respectively, of the inherited variation in disease outcomes.

We have learned several lessons from genomewide association studies. Although some risk loci that have been discovered through this approach encompass genes that had been previously impli-

cated, most of such loci implicate genes that had not been thought to have a role in conferring disease risk. Many loci show association with cardiovascular disease across groups of differing ancestry, and most cardiovascular traits are influenced by a large number of loci. However, limitations of genomewide association studies have prevented immediate translation of these findings into clinical practice, since each variant has a very small effect and is therefore not useful for prediction. Moreover, the implicated variants are rarely themselves the causal variants; rather, they are linked to the true causal variants, and identification of the latter usually warrants a great deal of additional work.

TARGETED AND GENOMEWIDE DNA SEQUENCING

The next generation of genomic approaches is upon us, thanks to the increasing efficiency and decreasing cost of sequencing technology. Deep DNA sequencing is performed with the use of miniaturized technology that simultaneously sequences multiple areas of the genome. This approach is used to sequence candidate regions and specific components of the human genome, such as exons or noncoding DNA. Sequencing studies in community-based cohorts have shown that at least 1 of every 64 persons carries a functional mutation in one of three genes (*NCCT*, *NKCC2*, or *ROMK*) that is associated with clinically significant alterations in blood pressure[57] and that there is a striking excess of nonsynonymous variants in the gene encoding adipokine (*ANGPTL4*) in persons with low triglyceride levels.[58] Targeted sequencing in a population with extreme values of LDL cholesterol identified variants in *PCSK9* that occur in up to 3% of the population. Such variants are associated with a low LDL cholesterol level and a decreased risk of incident coronary artery disease.[59] A sequencing study of *FAAH* and *MGLL* at extremes of the body-mass index uncovered several rare variants in promoter and enhancer regions of these genes, suggesting that sequence variation may regulate extreme obesity.[60]

Target genes for sequencing also include those identified by genomewide association studies that

The New England Journal of Medicine
Downloaded from nejm.org at VIRGINIA COMMONWEALTH UNIV on December 1, 2011. For personal use only. No other uses without permission.
Copyright © 2011 Massachusetts Medical Society. All rights reserved.

are associated with cardiovascular disease and its risk factors. Resequencing of exons in *APOA5*, *GCKR*, *LPL*, and *APOB* — genes that are implicated in hypertriglyceridemia — revealed twice as many rare missense or nonsense variants in persons with high triglyceride levels than in control subjects, corresponding to a carrier frequency of 28.1% in affected persons and 15.3% in control subjects.[61]

Whole-exome sequencing has uncovered genetic variants in persons with rare forms of diseases that affect blood pressure and circulating blood lipids, including a missense mutation in *SLC26A3* (a congenital chloride diarrhea locus) in a patient with a suspected diagnosis of the renal salt-wasting disease Bartter's syndrome,[62] a variant in *ANGPTL3* in a family with familial combined hypolipidemia,[63] and variants in *BAG3* in families with familial dilated cardiomyopathy.[64] Whole-exome sequencing in large populations may help to identify rare genetic variants in relatively common cardiovascular diseases, such as early myocardial infarction, that confer a major risk of complications and death and for which there is good evidence of heritability; indeed, this is a major focus of whole-exome sequencing at present. Whole-genome sequencing has also confirmed single-gene disease variants in families with rare diseases,[65] including mutations in *ABCG* in an infant with severe hypercholesterolemia.[66]

CARDIOVASCULAR DISEASE PATHWAYS

The best yield of genomewide association studies is the provision of insights into the biologic pathways — often previously unsuspected — that underlie causes of disease. Such insights have led to hypothesis-driven investigations of implicated pathways with the use of molecular, genetic, biochemical, and cellular approaches. The genetic control of myocardial infarction and lipids provides a case in point.

The initial findings that connected genetic variation in the 9p21 region with atherosclerotic progression and myocardial infarction caught cardiovascular scientists by surprise, because this region is devoid of genes that had previously been associated with coronary artery disease. Subsequent research has revealed possible mechanisms by which genes in this region may contribute to atherosclerosis. A recent report implicated the 9p21 risk interval in regulating the expression of cardiac *CDKN2A/B* expression genes.[38] Another report implicated inflammatory pathways through 33 gene enhancers located in the 9p21 region.[67] Two SNPs located in one of these enhancers disrupt a binding site for STAT1, a signal transduction protein that regulates inflammation. This enhancer locus physically interacts with the *CDKN2A/B* locus and an interval downstream of *IFNA21*, the gene that encodes interferon-γ in human vascular endothelial cells. The activation of interferon-γ affects transcriptional regulation of the 9p21 locus, including STAT1 binding, suggesting a link between genetic susceptibility to coronary artery disease and response to inflammatory signaling in vascular cells. Yet another driver of disease may be the aforementioned noncoding RNA element ANRIL.

Loci that are discovered by genomic approaches are also relevant to lipid biology and potential therapeutic targets. The gene encoding sortilin (*SORT1*) contains a common variant that creates a binding site for a transcription factor that when bound to this site alters liver expression of LDL cholesterol in humans. Transgenic studies have shown that mice with *Sort1* that contains the transcription-factor binding site have altered plasma levels of LDL cholesterol, suggesting a previously unknown regulatory pathway for LDL cholesterol.[68] A potentially therapeutic target was implicated by the discovery of a pair of common nonsense variants in *PCSK9* in patients of African descent. An estimated 2.6% of persons of African descent carry one of these variants, and each variant results in comparatively low lipid levels and a reduced susceptibility to myocardial infarction.[69] Humans who are homozygous for this null allele are healthy and have a reduced risk of myocardial infarction, suggesting that the absence of PCSK9 may be well tolerated and thus rendering PCSK9 an attractive drug target.

SNPs that more recently have been found to be associated with cardiovascular disease and its risk factors implicate components of pathways previously identified with risk factors for or mechanisms of the disease. For example, the 95 loci associated with levels of LDL and HDL cholesterol or triglycerides in more than 100,000 persons of European ancestry implicate nearly all the 18 genes that have previously been shown to be mutated

Genomewide association studies (GWAS) and gene sequencing represent discovery research. Findings from these studies stimulate further investigations in hypothesis-driven research and disease-risk prediction. Applications to clinical cardiovascular care will follow.

in rare mendelian lipid disorders.[43] Most of these loci were also associated with cardiovascular disease in persons of African descent and in persons of Asian descent. Some loci housed both common and rare variants; in such cases, the common variants explained more of the heritability.

An exciting approach is the use of induced pluripotent stem cells to model cardiovascular disease and test hypotheses generated from genomic studies. Two lines of induced pluripotent stem cells, which were generated from dermal fibroblasts in patients who had the long-QT syndrome with specific genetic mutations, have been differentiated into cardiomyocytes and are being used to investigate electrophysiological properties, such as action potentials and ion fluxes.[70,71]

PREDICTION, PREVENTION, AND TREATMENT

The improved understanding of cardiovascular pathophysiology that has been achieved through genetic discovery provides new opportunities for prediction, prevention, and treatment (Fig. 3). Genetic risk prediction is at an early stage, and insufficient evidence exists at present to warrant the use of a genetic risk score on the basis of SNPs identified through genomic approaches.[72,73] Additional research is needed to prospectively assess the utility of genetic risk scores in the prediction of cardiovascular disease, such as myocardial infarction and coronary artery disease, before clinical use. Some observers have suggested that 150 genes with odds ratios of 1.5 or 250 genes with odds ratios of 1.25 will be needed.[74] Future studies of genetic risk scores will probably require hundreds of associated SNPs (identified through genomewide association studies), combined with low-frequency risk alleles discovered through whole-genome sequencing, to provide evidence-based prediction.

Studies are under way to investigate the use of next-generation sequencing for the screening of rare forms of cardiovascular disease[75] and to annotate all mutations within an individual's genome.[76] Although the costs of accurate whole-genome sequencing are dropping dramatically, the costs of data analysis and storage remain high and are barriers to clinical implementation.

Loci that are uncovered by genomewide association studies, despite their modest effects, may

The New England Journal of Medicine
Downloaded from nejm.org at VIRGINIA COMMONWEALTH UNIV on December 1, 2011. For personal use only. No other uses without permission.
Copyright © 2011 Massachusetts Medical Society. All rights reserved.

have therapeutic implications. For example, a common variant at the *HMGCR* locus (with a prevalence of 40% among persons of European ancestry) is associated with a very modest elevation in the LDL cholesterol level (2.8 mg per deciliter [0.07 mmol per liter]).[43] There are no known rare mutations at this locus, presumably because they would be lethal. Yet the encoded protein, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, is the target of statin drugs, which reduce LDL cholesterol levels and the risk of myocardial infarction.

Pharmacogenomics has potential near-term application. Discoveries that are provided by genomewide association studies have strengthened the evidence for pharmacogenetic interactions in a number of commonly used cardiovascular drugs. Variants in *CYP2C9* and *VKORC1* explain up to 40% of the variation in the adjusted dose of warfarin, and the Food and Drug Administration (FDA) recently revised the label on warfarin to allow for genotype-specific dose ranges.[77] Variations in a cytochrome P-450 enzyme, *CYP2C19*, are associated with decreased antiplatelet efficacy and an increased risk of cardiovascular disease among patients taking the antiplatelet drug clopidogrel, which prompted an FDA warning and recommendations for a dose adjustment or use of alternative drugs in patients with this variant.[77]

Evidence of other pharmacogenetic interactions that may be clinically important is accumulating. Variation in the β_1-adrenergic–receptor gene, *ADRB1*, is associated with altered responsiveness to beta-blockade in heart failure.[78] A variant in *SLC01B1* has been implicated in statin-related myopathy.[79] Deep sequencing of variants and genes related to drug absorption, distribution, metabolism, and excretion may identify specific variants that contribute to the heterogeneity of responsiveness to cardiovascular drugs.

FUTURE DIRECTIONS

The field of cardiovascular genomics has two distinct goals: understanding biologic mechanisms and applying that knowledge to personalized medicine. Knowledge of molecular pathways can lead to improved therapeutics on a broad basis (regardless of the individual genotype) or at an individualized level (targeted specifically to the genotype). During the past 5 years, the discovery of hundreds of cardiovascular loci is a start. In the years to come, we will require studies of tens of thousands of patients with cardiovascular disease that combine tests of genomewide association (involving missense, rare, and common variants) with sequencing.[80] Functional studies are essential to characterize molecular and cellular pathways and to develop appropriately targeted therapies. Genomics is permeating biomedical research, and these genomic advances must proceed through basic discoveries, functional characterization, preclinical proof-of-principle studies, first-in-human studies, clinical trials, and regulatory approval. Cardiovascular science and medicine have made enormous strides over the past century, beginning with the brilliant elucidation of cardiovascular physiology and leading to molecular and cellular studies, with concurrent epidemiologic determinations of risk factors. The cardiovascular field is now primed for genomic medicine to make equal, if not greater, contributions.

This review focuses on recent research using genomics to examine lung carcinogenesis, histologic differentiation, and progression.

Keywords: adenocarcinoma; invasion; genomics; microarray; development

Lung cancer is the leading cause of cancer death in both men and women in the United States, despite its incidence being less than that of prostate cancer in men and breast cancer in women. With 166,000 deaths expected in 2008, the sum total of lung cancer deaths exceeds those of prostate, breast, and colon cancer combined (1). Prostate, breast, and colorectal carcinoma have all demonstrated significant improvements in 5-year survival over time and are currently 99, 88, and 64%, respectively. In contrast, the 5-year survival rate for lung cancer has remained relatively stable at 15%.

There are several potential explanations for the disparity between lung cancer survival and that of other common tumors, including late detection and histologic heterogeneity. Currently, over 75% of new lung cancer diagnoses are made in patients presenting with distant or regional metastatic disease (2). Histologically, prostate, breast, and colorectal carcinomas are uniformly adenocarcinoma and treatment is primarily determined by clinical stage, at times modified by results of molecular assays (3, 4). In contrast, only 30% of lung carcinoma is adenocarcinoma. Yet for the most part, until recently, non–small cell lung cancers (squamous, large cell, adenocarcinoma) were treated similarly, regardless of the biological heterogeneity associated with histology. It is likely that poor historical lung cancer response rates may in part be attributable to a relatively homogenous approach to a heterogeneous disease. Ongoing efforts are underway to identify clinically relevant biological properties of tumors that will facilitate individualized lung cancer treatment.

This research takes advantage of technical advances that allow rapid high-throughput assays to interrogate the genome (mRNA, microRNA, copy number, mutation analyses), proteome, and epigenome. In this review, we will focus on transcriptional profiling studies that have advanced our understanding of malignant transformation of lung epithelial cells and of lung cancer differentiation and progression. These advances have direct relevance to the goals of early detection, accurate prognostic assessment, and targeted therapy.

FIELD CARCINOGENESIS

Fifteen percent of lifetime smokers develop lung cancer, but 10% of lung cancers occur in never-smokers (5). In nonsmokers, exposure to secondhand smoke or to other lung carcinogens such as radon, asbestos, arsenic, or air pollution may be contributory. In both smokers and nonsmokers, genetic polymorphisms in genes associated with carcinogen metabolism, DNA damage repair, and cell cycle control may influence lung cancer susceptibility and modify the injury response associated with exposure to the dozens of carcinogens contained in tobacco smoke (6, 7). While the heritable component of lung cancer risk due to these genetic polymorphisms is most notable in early-onset cases occurring with less total smoke exposure, due to the limited number of genes studied, the overall attributable risk remains small even in this group of patients (7, 8). Recently, three genome-wide association studies identified a locus on chromosome 15q associated with lung cancer (9–11). The common locus variant near rs1051730 contains three genes encoding subunits of the nicotinic acetylcholine receptor (nAChR), CHRNA3, CHRNA5, and CHRNB4. The nAChR holoreceptor is a pentamer surrounding a gated channel responsive to ligands such as acetylcholine, nicotine, or its highly carcinogenic derivative 4(methylnitrosamine)-1-(3-pyridyl)-1-butanone (12). It is unclear whether the gene variant mediates susceptibility predominantly through influencing smoking behavior and nicotine dependence or through direct effects on lung tumor growth and suppression of apoptosis (13).

Because of tobacco smoke exposure, the bronchial epithelium of smokers is subject to field cancerization with alterations of airway cell DNA. Such alterations bring about oncogene activation, tumor suppressor gene silencing, and widespread loss of heterozygosity, all of which drive distinct gene expression signatures. While it is unclear which molecular alterations are required for neoplasia, in some instances, field carcinogenesis leads to malignant transformation of lung cancer progenitor cells. This malignant transformation may also require contributions from other systemic cell types such as bone marrow–derived stem cells (14, 15).

Microarray expression profiling has provided important information about cigarette smoke–associated lung carcinogenesis. Recently, we and others used gene expression profiling to identify gene signatures associated with cigarette smoking and lung adenocarcinoma in smokers and nonsmokers (16–20). Together, these results suggest that distinct cell transformation pathways and stromal tissue responses are involved in adenocarcinoma arising in smokers and nonsmokers (21). Observational studies using microarray analyses to profile bronchial epithelial cells obtained from bronchoscopic brushings of healthy smokers and nonsmokers identified overexpression of antioxidant genes and genes associated with xenobiotic metabolism by cells obtained from smokers (22, 23). However, these changes appeared to be potentially reversible when evaluated in a comparison of current versus former smokers. This transient genomic response to injury has been confirmed by *in vitro* studies using human bronchial epithelial cells exposed to cigarette smoke condensate and by *in vivo* rodent models of cigarette smoke exposure (24).

In addition, a field defect in smokers closely associated with lung cancer was reported by Spira and colleagues, who acquired gene expression signatures from nonmalignant bronchial cell brushings in a large number of smokers with and without lung

Figure 1. Comparison of gene expression of human lung tumors with genes temporally expressed during lung development suggests a recapitulation of developmentally regulated pathways. Nearest neighbor analysis was used to classify and rank murine (Mu11k) gene markers associated with two groups associated with lung development stage. Each *row* in the *heat map* (*middle panel*) shows gene expression over time for murine genes. Lung development stages represented by Group 1 (Days E12–E18, *top panel*) and Group 2 (Postnatal Day 1–Adult, *lower panel*) highly expressed genes are pseudoglandular/canalicular and terminal sac/alveolar, respectively. The corresponding human histology gene orthologs for large cell carcinoma are indicated in *red*, adenocarcinoma in *blue*. Specifically, genes expressed by large cell carcinoma mirror those expressed during the early pseudoglandular and canalicular stages of lung development, while those expressed by adenocarcinoma are predominantly expressed during the later terminal sac and alveolar stages.

cancer and observed that signatures from uninvolved cells in patients with cancer were distinct from those obtained from healthy smokers (25). This suggests that an epithelial "field defect" typically associated with cigarette smoke exposure may be specific for cancer. If validated prospectively, molecular testing of epithelial cells acquired throughout the aerodigestive tract may provide useful information for risk assessment.

GENOMICS OF LUNG CANCER DIFFERENTIATION AND PROGRESSION

Lung Developmental Pathways in Lung Cancer

Current paradigms suggest that lung carcinomas arise from pluripotent stem and progenitor cells capable of differentiation into one or several histologic cell types. These paradigms suggest that lung tumor cell ontology is determined by the consequences of gene transcriptional activation and/or repression events that recapitulate embryonic lung development (26, 27). The hypothesis that lung cancer arises from aberrant expression of genes involved in lung development is supported by gene expression studies demonstrating similarities between signatures obtained from human lung tumors and signatures characteristic of normal lung development (Figure 1). In an analysis of 32 non–small cell lung carcinoma (NSCLC) specimens and 7 normal specimens, unsupervised hierarchical analysis segregated tumors on the basis of histologic type and differentiation (28). Supervised clustering analysis of tumors identified numerous genes with known important function in embryonic lung development. Comparison of human lung tumor histology classifiers with genes temporally activated during mouse lung development reveals that genes expressed by large cell carcinoma (LCC) are similarly expressed during the early pseudoglandular and canalicular stages of lung development, while those expressed by adenocarcinoma mirror those expressed during the later terminal sac and alveolar stages. In addition to highlighting the expression of proliferation-associated genes by LCC and of differentiation-associated genes by adenocarcinoma, these results suggest a recapitulation of developmentally regulated pathways in lung tumors.

Similar observations were reported by Bonner and colleagues, who compared gene expression profiles of human lung tumors with those obtained from a murine model of lung adenocarcinoma (29). Liu and colleagues (30) found that genes associated with early lung development were more often expressed by small cell lung carcinoma (SCLC) and by tumors associated with poor prognosis. In addition, Glinsky and colleagues reported that a gene signature of "stemness" derived from BMI-1–regulated genes in normal stem cells is associated with metastasis and survival in several tumor types, including NSCLC (31). Taken together, these observations suggest that poor differentiation is linked to molecular parameters of early development representing lung stem and progenitor cell programs, and that gene signatures of these phenotypes are important for lung cancer differentiation, progression, and clinical outcome.

Neuroendocrine Tumors

One of the first studies using gene expression profiling to examine lung cancer histologic diversity compared carcinoids and small cell carcinoma tumors (32). Despite sharing neuroendocrine differentiation, the molecular profiles suggested different cells of origin for these tumor types. This molecular distinction was supported by a subsequent study from Bhattacharjee and colleagues (33) showing two distinct clusters of small cell carcinoma and carcinoid tumors, with small cell carcinoma characterized by frequent expression of proliferation markers such as MCM2, PCNA, MCM6, and thymidylate synthase. This was later confirmed by Virtanen and coworkers (34), who identified a carcinoid subgroup distinct from high-grade neuroendocrine carcinomas. Interestingly, large cell neuroendocrine carcinoma, a high-grade neuroendocrine carcinoma, was not readily distinguishable from small cell carcinoma by gene expression profiling. This observation suggested that despite being classified as an NSCLC subtype, large cell neuroendocrine carcinoma bears more similarity to small cell carcinoma than to other NSCLC subtypesn and illustrates how gene expression profiling can explain similar clinical features observed in histologically distinct tumors.

Squamous Cell Carcinoma

Researchers have examined gene expression profiles of squamous cell carcinomas (SCC) of the lung to address three major areas of concern: (*1*) to account for the histologic heterogeneity of NSCLC and to differentiate squamous cell carcinoma from other subtypes, (*2*) to identify prognostic factors specific to squamous cell carcinoma, and (*3*) to aid in distinguishing primary pulmonary SCC from metastatic SCC of the head and neck (HNSCC).

Several studies have identified gene expression profiles that distinguish pulmonary adenocarcinoma from pulmonary SCC (35–38). Notably, a shared set of genes encoding cytokeratins and cell adhesion proteins consistently distinguish squamous cell carcinoma from adenocarcinoma. These classifiers include cytokeratin 14 and components of desmosomes, hemi-desmosomes, and gap junctions, such as integrins ITGB4, desmocollin, and desmoplakin.

A consistent finding of unsupervised clustering analysis in pulmonary SCC is the generation of two clusters not attributable to histology, differentiation, or stage (39, 40). Rather, these clusters were enriched in prognosis associated genes encoding

Figure 2. Classification of lung adenocarcinoma reflects progression along a spectrum of invasiveness spanning epithelial atypia, bronchioloalveolar adenocarcinoma (BAC), BAC with foci of microinvasion, and invasive adenocarcinoma. In cells with repression of TGFβ-RII (*lower panel*), signaling through the Smad pathway is abrogated (*right*). Invasiveness is mediated through noncanonical signaling pathways that require RANTES (*left*).

proteins with function in the cell cycle and proliferation. Larson and colleagues (41) compared gene expression profiles of node-negative SCC tumors (N0) with signatures obtained from tumors with ipsalateral hilar or peribronchial nodal involvement (N1) via direct nodal invasion and with signatures obtained from N1 tumors with regional lymph node metastases via lymphatics, and found that N1 tumors with direct lymphatic invasion were similar to N0 tumors and distinct from N1 tumors with lymphatic spread, both in terms of molecular features and prognosis.

Although immunohistochemistry panels are effective in determining a site of primary origin for adenocarcinoma, equally effective panels do not exist for squamous cell carcinoma. Because primary SCC of the lung must be distinguished from metastatic HNSCC, this poses a diagnostic dilemma in patients with a history of HNSCC who subsequently develop a pulmonary nodule. Toward this end, Talbot and colleagues (42) developed a 500-gene classifier that distinguished pulmonary SCC from SCC of the tongue. In addition, Vachani and colleagues (43) used a training set of 18 HNSCC and 10 pulmonary squamous cell carcinomas to develop a 10-gene profile to distinguish these two tumor types. This classifier was validated on 122 subjects from previously published independent datasets, with 96% accuracy. Using real-time PCR, they correctly classified 12 independent samples as either of head and neck or pulmonary origin. These studies did not use microdissection; thus, it is possible that the signal from the host tissue may confound interpretation of gene signatures of tumor origin. However, if validated by others using microdissected specimens, these genomic classifiers hold promise for addressing important clinical staging issues in squamous cell carcinoma.

Adenocarcinoma

Somatic DNA alterations including mutations, amplifications, deletions, and translocations are common in tumors and are required for the activation of oncogenes and the inactivation of tumor suppressor genes that drive carcinogenesis. Large-scale efforts to systematically characterize these alterations in lung cancer and other tumors (44, 45) have provided insights into DNA structural alterations in non–small cell lung cancer. Adenocarcinoma, the most frequent histologic subtype of NSCLC, is characterized by multiple somatic DNA alterations. Recently, Weir and colleagues comprehensively examined DNA copy number alterations in 371 lung adenocarcinoma specimens (46) and found that the top focal regions of amplification and deletion included 14q13.3, 12q15, 8q24.21, 7p11.2, and 8q21.13. These results confirmed amplifications and deletions reported in other smaller studies, and also identified novel alterations such as amplification of the transcription factor TTF-1 on chromosome 14q13.3. *TTF-1* encodes thyroid transcription factor 1, a member of the Nk-2 homeobox family that binds to and activates the promoter of thyroid- and lung-specific genes. Interestingly, other groups using similar approaches also identified TTF-1 amplification as a frequent lung adenocarcinoma alteration, thus providing independent validation of this finding (47, 48). Together, these observations link lung tumor differentiation states and histologic grade with epithelial cell developmental pathways (28, 49), and suggest that these DNA amplification events are important in mediating lung cancer initiation, differentiation, and progression.

Lung Adenocarcinoma Invasion

Lung adenocarcinoma, the most frequent histologic type of NSCLC, is heterogeneous. Histologically, subclassification of adenocarcinoma is based upon World Health Organization (WHO) criteria, determined predominantly by cell morphology and growth pattern, along a spectrum including noninvasive bronchioloalveolar carcinoma (BAC), adenocarcinoma with mixed subtypes (AC-Mixed), and pure invasive adenocarcinoma (IAC) (50). Lung cancer metastasis represents the final step of a complex sequence composed of invasion (loss of cell–cell adhesion, increased cell motility, and basement membrane degradation), vascular intravasation and extravasation, establishment of a metastatic niche, and angiogenesis. Recent research has focused on characterizing the molecular mechanisms and clinical implications of adenocarcinoma invasion, the initial step of metastasis.

Paralleling malignancies in other organs, such as breast and cervix, where tumors are defined as noninvasive (*in situ* carcinoma), microinvasive (microscopic invasion), or as invasive carcinomas, the extent of the invasive component seen in lung adenocarcinoma is associated with clinical outcomes. Notably, this is most relevant in the lung for adenocarcinoma, because the noninvasive component is generally minimal in squamous cell carcinoma and often absent in large cell carcinoma. The clinical importance of lung adenocarcinoma invasion is supported by several recent studies (51–56) indicating that the risk of death in noninvasive BAC tumors is significantly lower than that of pure invasive tumors and in tumors with less than 0.6 cm of fibrosis or linear invasion. These results suggest that the prognosis of BAC is favorable, and suggest a similarly favorable prognosis for the subset of AC-Mixed subtype tumors with limited invasion (<6 mm).

We (57) and others (58–60) have used microarray gene expression profiling of lung adenocarcinoma tumors to identify signatures associated with histologic subtype and invasion. The results of unsupervised analyses are striking in that in each instance, tumors segregate into three major clades composed predominantly of BAC, AC-Mixed subtype, and pure invasive tumors, providing biological plausibility for the notion that these adenocarcinoma subtypes are distinct tumors. Taken together with the clinical data indicating distinct prognoses for each subtype, these studies have motivated consideration of revising the WHO lung adenocarcinoma classification scheme to reinforce the designation of purely noninvasive tumors and to create a designation for minimally invasive tumors.

To identify the molecular pathways important in mediating the acquisition of invasion by lung adenocarcinoma, we performed supervised analysis of mRNA microarray data to identify genes differentially expressed in noninvasive BAC and in AC-mixed type tumors. Among the genes differentially expressed in the progression from BAC to invasive tumors was the type II transforming growth factor β receptor (*TGF*β*RII*), which was less highly expressed by AC-Mixed and solid invasive tumors compared with BAC. This finding, which suggested that *TGF*β*RII* repression was required for lung adenocarcinoma invasion, is supported by genetic models combining targeted deletion of *TGF*β*RII* with other oncogenic events such as Apc mutation in colon tumors and Kras mutations in pancreatic and oropharyngeal carcinomas (61–63). The phenotypes of these *TGF*β*RII*-deficient cancer models clearly demonstrate the importance of TGF-β signaling in tumor invasion, yet the downstream signaling mechanisms are undefined.

We used a tumor cell invasion system and microarray analysis to identify and characterize downstream mediators of TGF-β signaling important for lung adenocarcinoma invasion (57). Among potential mediators identified was the chemokine CCL5 (RANTES [regulated on activation, normal T cell expressed, and presumably secreted]), which is upregulated by invasive tumors and *TGF*β*RII* knockdown cells. RANTES is involved in immunoregulatory and inflammatory processes and is transcribed and secreted not only by T cells, other inflammatory cells, and stromal cells, but also by tumor

TABLE 1. RECENT GENE EXPRESSION PREDICTORS OF NON–SMALL CELL LUNG CANCER OUTCOME

Classifier	Histology	Genes	Outcome	Platform
Duke Metagene (69)	NSCLC, Stages I, II, III	79	Recurrence	Affymetrix U133A
NCI Cytokine (72)	Adenocarcinoma, Stages I, II, III, IV	15	Lymph node metastasis and survival	RT-PCR
Milan 10 gene (73)	Adenocarcinoma, Stage I	E2F1, E2F4, HOXB7, HSPG2, MCM6, NUDCD1, RRM2, SERPINB5, SF3B1, SCGB3A1	Overall Survival	RT-PCR
Taiwan 5 gene (70)	NSCLC Stages I, II, III	*DUSP6, ERBB3, MMD, STAT1, LCK*	Overall and Relapse Free Survival	RT-PCR
Toronto 3 gene (74)	NSCLC Stages I, II, III	*CCR7, HIF1A, STX1A*	Overall Survival	RT-PCR

Definition of abbreviation: NSCLC = non–small cell lung cancer.

cells and normal bronchial epithelium. RANTES is a ligand for chemokine receptors CCR1, CCR3, CCR4, and CCR5, which are expressed on epithelial cells, macrophages, lymphocytes, dendritic cells, and stromal cells (64–67). Inhibition of RANTES signaling was found to be associated with abrogation of tumor invasion, suggesting that RANTES is required for invasion in *TGFβRII* repressed lung adenocarcinoma cells (Figure 2). The clinical significance of this pathway is further supported by the finding that tumor expression of both RANTES and CCR5 by a large panel of lung adenocarcinoma is associated with patient survival. These studies illustrate how information gained from global expression profiling of tumors can be used to identify key pathways and genes mediating tumor growth, invasion, and metastasis.

Gene Expression Predictors of Lung Cancer Survival

Proof of concept that tumor mRNA profiling provides clinically significant information regarding patient outcome after resection has been established. The promise of this approach to segregate tumors and to direct patient treatment based on these signatures is being prospectively tested in two breast cancer clinical trials. For NSCLC, several predictors have been developed, which for the most part are based on methodologically sound approaches that include independent validation. As indicated in Table 1, the results of these studies are heterogeneous both in terms of the number of genes in the predictors and in the specific genes included in each signature. This heterogeneity is expected, given differences in study design, assay platform, tumor histology, and patient selection. Subsequently, Shedden and colleagues published the results of a large, multicenter, blinded evaluation of several genomic signatures of prognosis in 442 adenocarcinomas (68). The addition of clinical covariates enhanced the performance of novel signatures, which performed slightly better than previously published signatures (69, 70). None of the signatures performed significantly better than the others. This landmark study is a model for the meticulous handling of challenges inherent in translational cancer genomic studies, and for its vast data repository of clinical and pathologically annotated data that now is available for testing of new signatures and hypotheses. It remains unclear which genomic predictor of prognosis is best or whether specific genes or entire signatures are most important in predicting outcome. Independent prospective evaluation of the predictive accuracy of these signatures, prospective clinical trials, and application to small biopsy specimens (71) are appropriate and will be required to extend this important area of research.

Gene expression profiling studies of lung tumors not only provide important information regarding prognosis and survival, but also help to identify potential therapeutic targets by offering key insights into how genetic alterations affect lung tumorigensis and metastasis. As medicine becomes increasingly reliant on genomic information, these studies hold much promise for the diagnosis and treatment of lung cancer.

Conflict of Interest Statement: A.C.B. is a co-inventor involved in a patent application "Gene expression profiles correlating with histology and prognosis" measuring gene expression of a set of genes with positive correlation with histologic subtype and prognosis. To date, no financial benefit has been derived from this application. R.L.T. does not have a financial relationship with a commercial entity that has an interest in the subject of this manuscript. C.A.P. received $125,000 in 2006–2007 from Philip Research, NA as research grants and is co-inventor for a pending patent filed by Columbia University for expression profiles correlating with histology and prognosis.

Received August 29, 2012; Revised October 15, 2012; Accepted October 20, 2012

ABSTRACT

Alterations in cancer genomes strongly influence clinical responses to treatment and in many instances are potent biomarkers for response to drugs. The Genomics of Drug Sensitivity in Cancer (GDSC) database (www.cancerRxgene.org) is the largest public resource for information on drug sensitivity in cancer cells and molecular markers of drug response. Data are freely available without restriction. GDSC currently contains drug sensitivity data for almost 75 000 experiments, describing response to 138 anticancer drugs across almost 700 cancer cell lines. To identify molecular markers of drug response, cell line drug sensitivity data are integrated with large genomic datasets obtained from the Catalogue of Somatic Mutations in Cancer database, including information on somatic mutations in cancer genes, gene amplification and deletion, tissue type and transcriptional data. Analysis of GDSC data is through a web portal focused on identifying molecular biomarkers of drug sensitivity based on queries of specific anticancer drugs or cancer genes. Graphical representations of the data are used throughout with links to related resources and all datasets are fully downloadable. GDSC provides a unique resource incorporating large drug sensitivity and genomic datasets to facilitate the discovery of new therapeutic biomarkers for cancer therapies.

INTRODUCTION

There is compelling evidence that alterations in cancer genomes can strongly influence clinical responses to anticancer therapies. Indeed, there are now several examples where genomic changes can be used as molecular biomarkers to identify patients most likely to benefit from a treatment. For example, the use of drugs to target the protein product of the *BCR–ABL* translocation in chronic myeloid leukemia, or the *BRAF* gene in malignant melanoma, has transformed the treatment of these diseases and substantially improved survival rates (1,2). Despite these notable successes, many cancer drugs in use or development have not been linked to specific genomic markers that could direct their clinical use to maximize patient benefit. Moreover, even among appropriately selected patients, a poorly explained range of clinical responses is observed (2,3). Thus, there exists a need for the development of new and improved biomarkers to guide therapies and ultimately improve clinical responses.

Recent years have seen significant advances in our understanding of the molecular nature of cancer (4). This has been driven in part by advances in high-throughput technologies and, in particular, DNA sequencing technologies that allow us to sequence on a scale that was previously unthinkable. In the near future, sequencing efforts will provide a complete description of the genomic changes that occur in many cancer subtypes. A complete list of the repertoire of cancer genes will provide profound insights into the origins, evolution and progression of cancer and will act as an impetus for the development of new cancer therapies.

To exploit this increased understanding, preclinical studies that link the genomic complexity of cancer with functional readouts such as drug sensitivity are required. Cancer cell lines derived from naturally occurring tumours have been generated from many different cancer types and in many respects recapitulate the tissue type and genomic context of cancer. They are a facile system for experimental manipulation and are a standard research tool in molecular biology and drug discovery. Significantly, several studies have used cancer cell lines to link pharmacological data with genomic information and helped define therapeutic biomarkers (5–7). Collectively, these studies have demonstrated that pharmacogenomic profiling in cancer cell lines can be used as a biomarker discovery platform to guide the development of new cancer therapies.

The Genomics of Drug Sensitivity in Cancer (GDSC) database (www.cancerRxgene.org) is designed to facilitate an increased understanding of the molecular features that influence drug response in cancer cells and which will enable the design of improved cancer therapies. GDSC holds and annotates large datasets on drug sensitivity in cancer cells and links these data to detailed genomic information to facilitate the discovery of molecular biomarkers of drug response. The website is designed to provide straightforward access to querying the database, and interactive graphical interfaces are used throughout to provide readily interpretable summaries of data and analyses.

DATABASE CONTENT

The GDSC database is based on three types of datasets as described in the following sections.

Cell line drug sensitivity data

Cancer cell line drug sensitivity data are generated from ongoing high-throughput screening performed by the Cancer Genome Project at the Wellcome Trust Sanger Institute (WTSI) and the Center for Molecular Therapeutics at Massachusetts General Hospital using a collection of >1000 cell lines (7). Compounds selected for screening are anticancer therapeutics encompassing both targeted agents and cytotoxic chemotherapeutics. They are comprised of approved drugs used in the clinic, drugs undergoing clinical development and in clinical trials and tool compounds in early phase development. They cover a wide range of targets and processes implicated in cancer biology including receptor tyrosine kinase signalling, cell cycle control, DNA damage response and the cytoskeleton. Compounds are sourced from commercial vendors or provided by collaborators in academia, biotech and the pharmaceutical industry.

Cell line drug sensitivity is measured using fluorescence-based cell viability assays following 72 h of drug treatment. Dose–response curves are fitted to fluorescence signal intensities over nine drug concentrations (2-fold dilution series) to derive a multi-parameter signature of drug response. Values reported on the website include the half maximal inhibitory concentration (IC_{50}), the slope of the dose–response curve and the area under the curve for each experiment.

The current release of GDSC (release 2, July 2012) includes drug sensitivity data for 138 anticancer compounds screened across a range of 329–668 cell lines per drug (mean = 525 cell lines per drug) representing 73 169 cell line–drug interactions. This is the largest public resource available on drug sensitivity in cancer cells. Screening is ongoing and the objective is to screen these compounds, as well as additional compounds in the future, across the entire collection of >1000 cell lines. Data release occurs every 4 months and with each release, these results are updated with new data for existing drugs, as well as data for newly screened drugs.

Genomic datasets for cell lines

The total collection available for screening includes >1000 different cancer cell lines. These have been selected to represent the spectrum of common and rare types of adult and childhood cancers of epithelial, mesenchymal and haematopoietic origin. The cell lines have been extensively genomically characterized as part of the cancer cell line project from the Cancer Genome Project at the WTSI. The genomic datasets currently available for each cell line include information on somatic mutations in 75 cancer genes, genome wide gene copy number for amplification and deletion, targeted screening for seven gene rearrangements, markers of microsatellite instability, tissue type and transcriptional data. Using various statistical approaches as described below, genomic datasets are used together with drug sensitivity data for each cell line to identify genomic biomarkers of drug response. Genomic datasets within GDSC are obtained and updated directly from the Catalogue of Somatic Mutations in Cancer (COSMIC) database, a comprehensive freely available resource for the annotation and presentation of somatic mutations in cancer (8).

Analysis of genomic features of drug sensitivity

An essential component of the GDSC database is the systematic integration of large-scale genomic and drug sensitivity datasets. To identify genomic markers of drug response, we currently use two complementary analytical approaches (7). A multivariate analysis of variance (MANOVA) is used to correlate drug sensitivity (IC_{50} values and slope of the dose–response curve) with genomic alterations in cancer including point mutations, amplifications and deletions of common cancer genes, cancer gene rearrangements and microsatellite instability. The MANOVA identifies individual genomic features associated with drug sensitivity and for each drug–gene association reports a size effect and statistical significance of the association.

We also apply elastic net regression, a penalized linear modelling technique, to identify multiple interacting genomic features influencing each drug response. Genomic data used in the elastic net analysis include all of those used in the MANOVA and also incorporate genome-wide transcriptional profiles and tissue type. The elastic net selects which of these features are associated with drug response as measured by IC_{50} values across the cell line panel. For each drug, a feature list is built comprised of mutations, transcripts and tissue with an effect size assigned to each.

A more detailed description of the different statistical analyses performed, as well as guidance on interpreting the results, can be found on the 'Help & Documentation' webpages under the 'statistical analysis' tab.

DATA ACCESS

Querying the GDSC database

The website is focused on presenting cell line drug sensitivity data and genomic correlates of drug sensitivity. Although data on the genomic characterization of the cell lines are available through the GDSC website, these data are presented in more detail within the COSMIC database.

To facilitate data interpretation, graphical representations with interactive features are used wherever possible. Querying the database is primarily based on either specific screening 'Compounds' or 'Cancer Genes' in the 'Browse our data' section of the homepage (Figure 1). Browsing by 'Compounds' displays a list of drug names together with their associated synonyms, putative therapeutic target(s), the number of cell lines screened for each drug (sample size) and date of the most recent data update for each compound. A link to the PUBCHEM database of chemical structures is provided (9). By clicking a specific drug name, users enter the individual drug page where drug sensitivity and genomic correlation data are presented.

Similarly, browsing 'Cancer Genes' leads to a list of cancer genes identified by their HUGO name. This page provides direct links to the COSMIC page for the gene and to the UniProt databases for further protein information (10). Clicking on the gene name accesses the drug sensitivity and genomic correlation data on the individual gene page.

It is also possible to query the database using a 'Search' function (Figure 1). The 'Search' box accepts queries based on compound (including synonyms), cancer gene or cell line name. An auto-completion feature enables users to quickly select their drug, gene or cell line of interest. The search result page lists matching compounds, cancer genes or cell lines with links to the detailed drug/gene page of the website. In the case of cell line matches, links are provided to detailed cell line information within COSMIC.

Data analysis and visualization

Screening data and genomic correlations are accessed through specific drug or gene pages (Figures 2a and 3). The top panel provides drug or gene information and links to PUBCHEM, COSMIC and UniProt databases as appropriate. Notably, the top panel also provides links to relevant help pages to explain the data and analyses performed. Additional information is also available from the 'Help & Documentation' link found in the header at the top of all pages. The actual screening data and analyses are presented in the bottom panel of a drug/gene page and are split into the following tabs: Volcano plot, Volcano data, Elastic net (drug pages only), Scatter plots and Download data.

A volcano plot is used to visualize the correlation of drug sensitivity data with genetic events as calculated using the MANOVA. The drug page shows a drug-specific volcano plot, which represents how different genomic changes influence response to a specific drug (Figure 2a). The gene page shows a gene-specific volcano plot, which represents the effect of a mutated cancer gene on the responses to all drugs analysed (Figure 3). For example, the

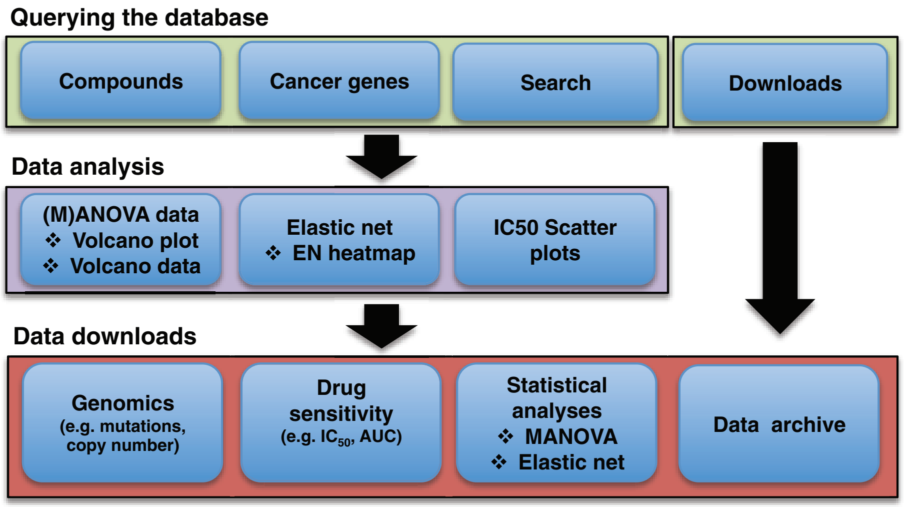

Figure 1. A schematic representation of the GDSC database structure and content. Data are accessed in a hierarchical fashion by either querying by screening compound or cancer gene of interest. This gives access to graphical representations of cell line drug sensitivity data and genomic correlations of drug response in multiple formats through either drug- or gene-specific pages. All data are freely available for download either through gene- or drug-specific pages, or as a whole through the download page.

Figure 2. Querying the GDSC database by compound name. Drug-specific pages demonstrate the effect of genomic features on cell line sensitivity to a particular drug. In this example, we show the effect of genomic features on sensitivity to the BRAF-inhibitor PLX4720. (**a**) A volcano plot representation of MANOVA results showing the magnitude (*x*-axis) and significance (*P*-value, log scale on inverted axis) for each cancer gene association. Each circle represents a single drug–gene interaction and the size is proportional to the number of mutant cell lines screened for each drug. For clarity, the *y*-axis is capped at $P = 1 \times 10^{-8}$ and a plus sign (+) next to a circle indicates that the *P*-value is smaller than this threshold. The dashed red line represents a Benjamini–Hochberg multiple testing correction for significance and only significant associations are coloured either green for drug sensitivity or red for resistance. (**b**) Elastic net analysis of genomic features associated with sensitivity to PLX4720. Features with negative effect size are associated with drug sensitivity and features with positive effect size are associated with drug resistance (all features are negative in this example). Mutation and tissue features are at the top of the heatmap to represent the presence (black) or absence (grey) of a mutation/tissue subtype. Below this are gene expression and copy number features with blue corresponding to lower expression or copy number, and red to indicate higher expression or copy number.

drug-specific volcano plot for the BRAF-inhibitor PLX4720 shows that mutations in the gene *BRAF* are significantly associated with sensitivity to this compound (Figure 2a). Conversely, the gene-specific volcano plot for *BRAF* shows that mutations in this gene are associated with sensitivity to multiple drugs including several different BRAF inhibitors (i.e. PLX4720, SB590885 and AZ628) (Figure 3). In both cases, the *x*-axis represents the magnitude of the effect of a gene–drug interaction on IC_{50} values across the cell lines screened and the *y*-axis is the significance of the interaction (*P*-value). By hovering over each circle, the following information is provided: genetic

Figure 3. Querying the GDSC database by cancer gene. Gene-specific pages show how a cancer gene mutation affects response to many drugs. A volcano plot representation shows results of the MANOVA analysis for drug sensitivity associated with *BRAF* mutations.

event sample size (i.e. the number of cell lines screened with a specific mutation), effect size and *P*-value. By clicking on an individual circle, it is possible to link to a scatter plot of cell line IC_{50} values for this association (see below). The volcano data tab represents the volcano plot data as a sortable table. Three buttons at the top of the table allow the download of the table in .csv, .tab or .xlsx file format.

Similarly, the elastic net tab contains a graphical representation of results from the elastic net analysis of drug sensitivity (Figure 2b). For effective visualization, a maximum of 10 significant features associated with drug response are shown. These may include tissue type, mutations in cancer genes, expression levels and gene copy number. Each graphic contains three elements: a bar plot of effect size for significant features (right-hand side), a heatmap of genomic features (central panel) and a second heatmap of IC_{50} values for the 20 least and most sensitive cell lines (bottom). For example, the elastic net analysis for BRAF-inhibitor PLX4720 identified mutations in the *BRAF* gene, the tissue-type skin, as well as several transcriptional features (*BCL2A1*, *GYPC* and *DAAM2*) as associated with drug sensitivity (Figure 2b). Unlike the MANOVA analysis, gene-specific correlations for the elastic net analysis are not represented since the EN describes how multiple genes affect drug sensitivity together.

The 'Scatter plots' tab shows a plot of cell line IC_{50} values to a drug. IC_{50} values are split into two populations according to a cell lines mutational status for a given gene that is significantly associated with the drug response (Figure 4). In the example provided, cell lines with a *BRAF* mutation are on average more sensitive to PLX4720 compared with *BRAF* wild-type cell lines (Figure 4). The table in the middle shows the statistics for the plot including sample size, and the mean and median IC_{50} values for the two populations (mutated or wild type). Additional functionality includes the ability of users to select which drugs (or genes from the drug-specific pages) to plot. It is possible to link directly to relevant scatter plots by clicking on circles within the volcano plot pages. Furthermore, by clicking on circles within scatter plots, cell line IC_{50} values are directly linked to the COSMIC database facilitating integration of drug sensitivity data with detailed cell line information such a tissue type, tumour histology and a description of cell line origin and genotype.

Download data

As the emphasis of the website is on the graphical representation of data both the volcano and scatter plots are downloadable as either .png or .svg files. In addition, the raw data are available to download in either .csv or .xlsx format. As described below, it is possible to download the data for a specific drug or gene on their associated pages, or to download the data from all of our analyses in a series of large spreadsheets.

On the drug page for a specific compound, the available downloads include (i) sensitivity data for the drug (a table of cell line IC_{50} values); (ii) genomic alterations in cell lines; (iii) genomic correlations with MANOVA and (iv) elastic net analysis of drug sensitivity. On a gene page a single data download is available, containing the

Figure 4. Scatter plot of cell line IC_{50} values and the effect of a cancer mutation. A scatter plot of cell line IC_{50} values for *BRAF*-mutated versus wild-type cell lines following drugging with PLX4720. Each circle represents the IC_{50} value for an individual cell line plotted on a logarithmic scale and the red line is the geometric mean of the population. Cell lines are colour coded to indicate whether the mutation is a coding mutation detected by sequencing, or an amplification or deletion detected by copy number analysis. The lower and upper brown lines indicate the minimum and maximum concentration in micro-molar of drug used for screening. Super-imposed on the scatter plot is a box-and-whisker plot showing the median, interquartile ranges and max and min for each plot. The central panel contains statistics for the plot and the right-hand table allows users to select which drug data to plot.

MANOVA correlation for how a gene correlates with drug response across the entire panel of compounds.

Rather than downloading drug- or gene-specific data, drug sensitivity and genomic datasets can also be directly downloaded as a whole through the 'Downloads' page. This can be directly accessed from the header on each page. Downloadable files include (i) cell line tissue type, drug sensitivity and genomic data used for the MANOVA; (ii) the MANOVA results for all compounds; (iii) A tissue-specific ANOVA to examine the effect of tissue type on drug response; (iv) the elastic net results for all compounds; (v) cell line genomic and transcriptional data used for elastic net analysis and (vi) a continuously updated list of cancer cell lines in our collection. Please note that some of these files contain a large number of columns and data will be lost if files are opened in Excel 2003 or earlier versions because the worksheet size is limited to 256 columns. The 'Downloads' page also provides access to archive files of previous data releases.

FUTURE WORK

The GDSC database will expand significantly in coming years as the size and complexity of datasets increase. The database currently contains data for ~75 000 experiments across 138 drugs and the amount of drug sensitivity data is expected to increase in size 2–3-fold within the next 2 years and even further in the future. This will include drug sensitivity data for many new cell lines to bring the total number to >1000 lines, and the inclusion of data for hundreds of newly screened anticancer drugs. Collectively, this will expand the number of different cancer subtypes and genotypes represented within the cell line collection, as well as the number of different drug targets interrogated by screening compounds.

Additional developments will see the further genomic characterization of the cell line collection to increase its utility as a resource. Notably, this will include whole-exome sequencing of all ~22 000 coding genes across the entire collection. Whole genome SNP6.0 copy number data currently include ~750 cell lines and this will be expanded to include the entire cell line collection. Similarly, basal transcriptional data are currently being updated to include the entire cell line collection using the latest Affymetrix human genome U219 mRNA expression array. These new genomic datasets, together with our expanding drug sensitivity datasets, will be incorporated into our analytical models to enhance our ability to identify therapeutic biomarkers predictive of drug response.

Large numbers of primary tumours across different cancer types are being extensively genomically characterized by systematic efforts such as the International Cancer Genomics Consortium. This will give us profound insights into the molecular taxonomy of cancer and, for the first time, enable us to directly assess the genomic similarity of our cell line models to primary tumours. Based on these comparisons, we will refine and expand the cell line collection to ensure that they are as representative as possible of primary tumours. Similarly, it is increasingly clear that patient responses to therapy can be highly variable even within pre-selected populations. We intend to systematically interrogate mechanisms of intrinsic resistance to clinical drugs by enriching the cell line collection with suitable *in vitro* models. An additional development will be an increased emphasis on drug sensitivity screening of low passage primary cultures derived from patient tumours. Collectively, these developments should further enhance our ability to model drug response and help address the fundamental question of intrinsic resistance to clinical cancer drugs.

The expansion of the database will likely require the development of new analytical tools to identify genomic biomarkers of drug response. This will involve the development of new statistical methods to interrogate the data and is likely to include the incorporation of pathway and tissue-based analyses of drug sensitivity. Similarly, the expansion will require new tools for mining and visualizing increasingly sophisticated and complex analyses.

DISCUSSION

Here, we have presented the GDSC database as a new resource for therapeutic biomarker discovery in cancer cells. Key features of the database include the largest resource of cell line anticancer drug sensitivity data publically available. In addition, the GDSC database integrates large genomic datasets with drug sensitivity information to identify putative therapeutic biomarkers for further preclinical validation. These data are presented using simple graphical representations and all data are freely available for download. The GDSC database will undergo significant expansion in coming years as drug sensitivity and genomic datasets increase in size and complexity.

The ultimate aim of the GDSC database is to facilitate the development of new cancer therapies through the preclinical identification of therapeutic biomarkers. The current approach to development of new cancer therapies is difficult, costly and time-consuming. For example, the time taken to develop a new drug is often >10 years and costs frequently exceed 1 billion US dollars. Moreover, despite this substantial investment, the level of attrition is very high with the majority of new drugs failing during clinical trials (estimated to be between an 80–95% failure rate) due to lack of efficacy or unacceptable toxicity (11). The preclinical identification of therapeutic biomarkers could significantly improve the design and ultimate success of clinical trials by permitting smaller, quicker and less costly trials in molecularly stratified patient populations most likely to benefit from treatment. By facilitating the preclinical identification of putative therapeutic biomarkers, the GDSC database is a valuable resource to enable the development of new rationally designed cancer therapeutic strategies incorporating molecular biomarkers.

ACKNOWLEGEMENTS

We would like to thank the members of the GDSC team for advice and discussion. We also thank Prasad Gunasekaran, Mingming Jia and Paul Bevan for their technical assistance.

Group A human rotaviruses (HRVs) are the major cause of severe viral gastroenteritis in infants and young children. To gain insight into the level of genetic variation among HRVs, we determined the genome sequences for 10 strains belonging to different VP7 serotypes (G types). The HRVs chosen for this study, D, DS-1, P, ST3, IAL28, Se584, 69M, WI61, A64, and L26, were isolated from infected persons and adapted to cell culture to use as serotype references. Our sequencing results revealed that most of the individual proteins from each HRV belong to one of three genotypes (1, 2, or 3) based on their similarities to proteins of genogroup strains (Wa, DS-1, or AU-1, respectively). Strains D, P, ST3, IAL28, and WI61 encode genotype 1 (Wa-like) proteins, whereas strains DS-1 and 69M encode genotype 2 (DS-1-like) proteins. Of the 10 HRVs sequenced, 3 of them (Se584, A64, and L26) encode proteins belonging to more than one genotype, indicating that they are intergenogroup reassortants. We used amino acid sequence alignments to identify residues that distinguish proteins belonging to HRV genotype 1, 2, or 3. These genotype-specific changes cluster in definitive regions within each viral protein, many of which are sites of known protein-protein interactions. For the intermediate viral capsid protein (VP6), the changes map onto the atomic structure at the VP2-VP6, VP4-VP6, and VP7-VP6 interfaces. The results of this study provide evidence that group A HRV gene constellations exist and may be influenced by interactions among viral proteins during replication.

Group A human rotaviruses (HRVs) cause severe gastroenteritis in children and are responsible for up to 600,000 deaths each year worldwide (37). The rotavirus genome consists of 11 segments of double-stranded RNA contained within a triple-layered capsid (39). In general, each gene segment encodes a single polypeptide, allowing rotaviruses to express five or six nonstructural proteins (NSP1 to NSP5 and sometimes NSP6) and six capsid proteins (VP1 to VP4, VP6, and VP7) (12). The inner layer of the virion is composed of the core lattice protein (VP2) and encases the viral RNA-dependent RNA polymerase (VP1), the RNA capping enzyme (VP3), and genomic RNA (39). The intermediate layer is made entirely of VP6, which is the most recognized group- and subgroup (SG)-specific rotavirus antigen used for classification purposes (12, 23). Comprising the outermost layer of the rotavirus particle, the capsid proteins VP7 and VP4 are involved in virus entry into the cell and elicit neutralizing antibodies during infection of a host (12, 23). Serotypes defined by these outer capsid proteins are referred to as G types (VP7) and P types (VP4) and, along with G/P genotypes, are a predominant method of characterizing individual group A rotavirus isolates (23, 30). To date, a total of 14 G types (19 G genotypes) and 14 P types (27 P genotypes) have been identified in nature (23, 30).

Molecular epidemiology studies suggest that HRV G-type strains G1 to G4 are the most prevalent and are often combined with P-type specificities P[4], P[6], and P[8] (13, 23). Nonetheless, other serotypes, some of which bear resemblance to animal rotaviruses, are emerging as important agents of human disease in certain geographical regions (11, 13). For example, recent reports indicate an increase in incidences of HRV serotypes G5 and G8 in developing countries in South America and Africa (25). Unusual HRV serotypes, such as G9 and G12, are being reported at high levels in many countries, including those that are industrialized (13, 43). Of the 19 known G genotypes, 11 of them have been isolated from patients hospitalized for gastroenteritis; genotypes G7 and G13 to G19 have so far been isolated only from animals (25). These epidemiological observations suggest that the circulating rotavirus population is diverse and evolving. However, aside from the genes encoding outer capsid proteins (VP7 and VP4), little is known about the genetic makeup of emerging and endemic HRV strains because very few full-genome sequences have been determined. The limited insight into nucleotide similarities among group A HRVs that we do have is based on the results of qualitative RNA hybridization assays. This approach assigns a viral isolate into one of three distinct genogroups when seven of its gene segments anneal with those of a genogroup prototype strain: Wa (G1P[8]), DS-1 (G2P[4]), or AU-1

(G3P[8]) (35). Of the three HRV genogroups, Wa and DS-1 are overwhelmingly prominent, whereas the AU-1 genogroup is extremely rare (34). Intragenogroup resemblances are often reflected in the antigenic properties of their VP6 proteins (SG-I versus SG-II) and the electrophoretic migration pattern of viral genome segments (short or long electropherotype) but not necessarily in their serotype specificities (34). For example, G3 HRV isolates have been categorized into each of the three genogroups (Wa, DS-1, and AU-1), suggesting that they are serotypically similar but genetically separate (34). The results of these hybridization studies reveal that the diversity of HRVs in nature is far greater and more complex than that indicated by serotyping alone. Still, genogroup analysis via RNA hybridization does not identify specific amino acid changes that distinguish proteins of one genogroup from another. With the increasing ease of genetic sequencing, studies aimed at comparative genomic analyses of HRV genogroups are warranted.

The factors that influence the emergence of new group A rotavirus serotypes and genogroups within the human population are not completely understood. Reassortment events, in which two distinct rotavirus strains exchange gene segments, are predicted to play a major role in generating diversity (13, 23). In support of this idea, strains with different serotypes and genogroup specificities have been found circulating together during a single rotavirus season, and coinfections of individuals with more than one rotavirus strain (some of animal origin) are reported with frequencies of up to 23% (14). As a result, rotaviruses are hypothesized to exist as a heterogeneous pool of reassortants that is under continuous extrinsic and intrinsic selection pressures (14). Maternal antibodies, previous infection, and vaccination are just some extrinsic, host-derived pressures that could lead to the emergence of novel HRV G/P types. Yet, there is also evidence suggesting that intrinsic selection pressures, such as the capacity of divergent rotavirus proteins to functionally interact during replication, are important in determining the emergence of reassortant strains. For instance, although the genes encoding VP7 and VP4 can segregate independently, certain combinations of G/P types seem preferred among naturally circulating HRVs; G1 is almost always associated with P[8], whereas G2 is commonly seen with P[4] (9). The existence of genogroups is also consistent with the idea that biases toward certain gene constellations among HRVs occur. In fact, independent segregation of genes between different genogroup strains, aside from those encoding VP7 and VP4, is uncommonly reported (49). It is possible that viral protein-protein interactions drive the intrinsic selection of HRV reassortant strains that can replicate better inside an infected cell. In other words, a Wa-like protein might function more effectively with another Wa-like protein than it would with a DS-1-like protein. To test this possibility, we need a more complete understanding of the genetic composition of proteins from group A HRVs belonging to different serotypes and genogroups.

The results presented in this report are part of a collaborative effort by our laboratory and others that resulted in the establishment of a classification system for all 11 group A rotavirus genome segments (30). Based on phylogenetic analyses of the nucleotide sequences, distinct genotypes were determined for each individual rotavirus segment. The results not only confirmed the G/P types of HRVs by use of appropriate percent identity cutoff values but also increased our understanding of the variation seen in the nine other rotavirus genes. The majority of analyzed HRV gene segments were assigned into genotypes that correlate with the previously described genogroup strains Wa (genotype 1), DS-1 (genotype 2), and AU-1 (genotype 3) (30). In this report, we present the history and detailed sequence characteristics of G-type laboratory reference strains D, DS-1, P, ST3, IAL28, Se584, 69M, WI61, A64, and L26. Our results are consistent with the idea that viral protein-protein interactions influence the extent of group A HRV diversity and the maintenance of preferred gene constellations.

MATERIALS AND METHODS

Cells and rotaviruses. Monkey kidney (MA104) cells were propagated in 199 medium supplemented to contain 10% fetal bovine serum, 1% penicillin-streptomycin, and 0.1% amphotericin B. Human cell culture-adapted rotavirus strains D (G1P[8]), DS-1 (G2P[4]), P (G3P[8]), ST3 (G4P[6]), IAL28 (G5P[8]), Se584 (G6P[9]), 69M (G8P[10]), WI61 (G9P[8]), A64 (G10P[14]), and L26 (G12P[4]) were generously provided by Y. Hoshino (NIH) and were used to infect MA104 cells after pretreatment with 10 μg/ml trypsin, as described previously (16). Infected cells were incubated in serum-free 199 medium for 24 to 72 h until cytopathic effect was visible.

RNA extraction, RT-PCR, and sequencing. Total cytoplasmic RNA was extracted from approximately 2×10^6 rotavirus-infected cells by use of Trizol-LS as described in the manufacturer's protocol (Invitrogen). RNA was denatured by incubation for 10 min at 94°C in a final concentration of 50% dimethyl sulfoxide. Denatured RNA (from approximately 1×10^4 infected cells) was then used as a template for reverse transcription (RT)-PCR to amplify cDNAs corresponding to regions of rotavirus gene 1, 2, 3, or 6 (encoding VP1, VP2, VP3, or VP6, respectively). For genes 5, 6, 9, 10, and 11, RT-PCR was performed using a SuperScript one-step RT-PCR system (Invitrogen). For genes 1 and 2 and genes 3, 4, 7, and 8, respectively, SuperScript II RT and Platinum *Taq* DNA polymerase (Invitrogen) were used according to the manufacturer's protocols. The PCR products were purified using a QIAquick PCR purification kit (Qiagen). In cases when nonspecific PCR bands were present, samples were electrophoresed in a 1% agarose gel, and specific cDNA products were excised and purified using a QIAquick gel extraction kit (Qiagen). The purified PCR products were then sequenced with an ABI Prism BigDye v3.1 terminator cycle sequencing kit (Applied Biosystems Group). The dye terminator was removed using Performa DTR (Edge Biosystems), and sequences were obtained with a 3100 genetic analyzer for genes 5, 8, and 11 or a 3730 DNA analyzer (both Applied Biosystems) for genes 1 to 4, 6, 7, 9, and 10.

For sequencing the 3′ ends of 69M and L26 gene 3 (approximately nucleotides 2155 to 2507) and the 3′ end of ST3 gene 7, the PCR products were ligated into the pGEM-T-Easy vector (Promega) and three independent clones were sequenced. For sequencing the 5′ ends of gene 4 for all of the viruses, PCR products were ligated into the pCR-TOPO-2.1 vector (Invitrogen). Strain A64 genes 10 and 11 were ligated to the pGEM-T-Easy vector and then cut with restriction enzymes BsmBI and MfeI (New England Biolabs), respectively, so that the duplicated genes could be sequenced accurately. Sequence files were analyzed and assembled using Sequencher 4.5 (Gene Codes Corporation).

The nucleotide sequences of the entire open reading frames (ORFs), as well as additional flanking sequences, were determined. Terminal primers were used for RT-PCR amplification, and therefore the extreme 3′ and 5′ termini were not determined de novo.

Amino acid alignments. Amino acid alignments were constructed with MacVector 8.1.2. (Accelrys) using ClustalW, BLOSUM Series, with the defaults set (open gap penalty of 10.0, extended gap penalty of 0.05, and delay divergence of 40%). GenBank accession numbers for the viruses used in this study are presented in Table 1.

RESULTS AND DISCUSSION

The nucleotide sequences of the gene segments for HRV G-type reference strains D, DS-1, P, ST3, IAL28, Se584, 69M, WI61, A64, and L26 were determined by automated sequencing. Table 2 summarizes pertinent features of these strains, as

well as those of other group A HRVs whose genome sequences have been reported to date. With a few exceptions, the individual genes/proteins for the 10 reference strains were assigned to genotypes that correlate with previously described genogroup strains Wa (genotype 1), DS-1 (genotype 2), and AU-1 (genotype 3) (30) (Fig. 1). This classification system afforded the opportunity to identify HRVs that are either (i) pure genogroup strains, with all of their proteins classified into a single genotype, or (ii) intergenogroup reassortants, with proteins of more than one genotype.

Wa genogroup (genotype 1) strains D, P, ST3, IAL28, and WI61. The Wa strain is one of the best-studied HRVs, in large part because it was the first to be grown successfully in culture and because it causes acute diarrhea in gnotobiotic piglets (51). The virus was isolated in the United States in 1974, and as the prototype for the Wa genogroup, the virus exhibits a long electropherotype and VP6 SG-II and VP2 SG-II specificities (50) (Fig. 1 and Table 2). Using the aforementioned classification system, we found that 5 of the 10 viruses (D, P, ST3, IAL28, and WI61) are genetically more similar to Wa than to either the DS-1 or the AU-1 strain (30) (Fig. 1). With the exception of VP4 and VP7, each of the proteins encoded by these five viruses can be classified as genotype 1. The observation that these HRVs do not encode proteins similar to the DS-1 and AU-1 genogroups (genotypes 2 and 3, respectively) suggests that they are not intergenogroup reassortants but instead can be viewed as pure Wa genogroup strains. The Wa-like strains D, P, and ST3 have been characterized over the years because they represent three of the four most common HRV G types (G1, G3, and G4, respectively). The VP7-encoding genes from these strains (in addition to that of the G2 strain DS-1) have been incorporated into the live-attenuated, multivalent rotavirus vaccines RotaTeq and RotaShield (37). The D and P strains were originally isolated in 1974 in the United States (Children's Hospital, Washington, DC) from infants suffering from gastroenteritis (24, 50). The ST3 strain was isolated in 1975 from an asymptomatic newborn in England (St. Thomas Hospital, London) (6, 50). Despite the importance of the D, P, and ST3 strains, their genome sequences have not been determined previously.

While the D, P, and ST3 strains represent more commonly circulating HRV serotypes, IAL28 and WI61 reflect globally emerging serotypes G5 and G9, respectively (Table 2). Strain IAL28 was isolated in 1992 from a child with diarrhea in Brazil

FIG. 1. Summary of HRV protein genotypes, genogroups, and reassortment incidences. Individual HRV strains analyzed in this study are listed at the top, with their corresponding genes/proteins aligned underneath. The VP7 and VP4 genotypes (G/P types) of the strains are listed. Colors indicate the genotype of each gene/protein, as described previously (30): green for Wa-like genotype 1, red for DS-1-like genotype 2, orange for AU-1-like genotype 3, and blue for animal RV-like genotypes. The single-letter abbreviation for each protein is indicated in parentheses (30). VP6 and VP2 SG specificities and NSP4 genotypes (A, B, and C) are classified according to previous studies (17, 26, 32). The NSP6 ORFs were found to be identical to that of the Wa strain (WT), truncated (Tr), or extended (Ex) (also see Fig. S3 in the supplemental material). Below each genome, the HRVs are classified as pure Wa genogroup strains (Wa), pure DS-1 genogroup strains (DS-1), a pure AU-1 strain (AU-1), or intergenogroup/interspecies reassortants (Re). The numbers of reassortment incidences (# RI) detected in this study for genes encoding VP1 to -3, VP6, and NSP1 to -5 are listed on the right.

and was initially shown to have dual G5-G11 antigenic determinants; this virus was later classified as a G5 strain based on sequence analysis (30, 48). Because G5 and G11 serotypes are commonly seen in pigs, IAL28 might represent an interspecies reassortant, with its VP7 gene coming from a porcine virus and its 10 other genes coming from a Wa genogroup HRV (48). Strain WI61 was recovered in 1983 from a child with gastroenteritis in the United States (Children's Hospital, Philadelphia, PA) (7). At the time of its isolation, only G1 to G4 serotypes had been identified in humans, and therefore WI61 represented the fifth G type to be discovered. With the recognition that the incidence of G9 HRV infections is steadily increasing, WI61 becomes a particularly important reference strain (44). In addition to those of D, P, ST3, IAL28, and WI61, the full-genome sequences of other Wa genogroup HRVs have been determined, including two G1P[8] strains (KU and Dhaka 16-03) and several G12 isolates: Dhaka 12-03 (G12P[6]), B4633-03 (G12P[8]), and Dhaka 25-02 (G12P[8]) (Table 1) (43, 50). Our analyses suggest that despite the differences in serotype specificities (i.e., G1, G3, G4, G5, G9, and G12), these HRVs are genetically similar viruses (Fig. 1). Thus, pure Wa genogroup viruses can bear a large number of VP7 serotypes.

DS-1 genogroup (genotype 2) strains DS-1 and 69M. Strain DS-1 is the well-known prototype for its genogroup and was isolated in 1976 in the United States (Children's Hospital, Washington, DC) from an infant with diarrhea (45, 50) (Table 2). Like many other strains belonging to the DS-1 genogroup, the virus has VP6 SG-I and VP2 SG-I specificities and a short electropherotype, the latter due to an extended gene 11 3′ untranslated region (UTR) (28). In addition to Wa-like strains D, P, and ST3, the VP7 gene of DS-1 represents one of the most predominant HRV serotypes (G2) and is included as a component of the tetravalent rotavirus vaccines. This is the first report of the full-genome sequence for this important vaccine-related strain.

Of the HRVs sequenced in this study, 69M is the only strain besides DS-1 that is classified as a pure member of the DS-1 genogroup (Fig. 1). 69M was isolated in Indonesia in 1980 from a child with diarrhea and is unusual in that, instead of the short electropherotype of most DS-1-like strains, 69M has a super-short electropherotype (19, 28, 29). The super-short migration pattern of the 69M genome is due to its gene 11 3′ UTR being twice the length of the already extended DS-1 gene 11 3′ UTR (28). Since 69M is a pure member of the DS-1 genogroup, all of the individual proteins encoded by 69M, with the exception of VP4 and VP7, can be classified as genotype 2. Other DS-1-like HRVs of which genome sequences are known include the Chinese isolate TB-Chen (G2P[4]) and the DS-1-like isolates DRC86 (G8P[6]) and DRC87 (G8P[8]), which are from the Democratic Republic of the Congo (5, 31). These results indicate that DS-1 genogroup HRVs can display VP7 proteins from diverse G types (e.g., G2 and G8), although seemingly not as diverse as the G types that are associated with Wa genogroup strains.

Intergenogroup reassortant strains Se584, A64, and L26. We found that three of the reference strains we sequenced, namely, Se584, A64, and L26, show proteins originating from more than one genotype. These three viruses encode mostly genotype 2 (DS-1-like) proteins but have a few proteins that can be classified as either genotype 1 or genotype 3 (Wa-like or AU-1-like, respectively). Strain AU-1 was isolated in Japan during the years 1981 to 1983, and based on the lack of RNA hybridization with the Wa or DS-1 probe, AU-1 became the prototype strain for a third HRV genogroup (34, 36). However, this genogroup is very rare, and with the exception of the prototype strain, no pure AU-1 HRVs have been isolated to date. The only other AU-1 genogroup strain recovered from a human is strain T152 (G12P[9]), which was discovered in Thailand and encodes only seven genotype 3 proteins (Fig. 1) (30, 42, 43). Interestingly, T152 expresses two proteins (NSP1 and NSP5) more closely related to animal rotaviruses, suggesting that this AU-1-like virus may represent an interspecies reassortant (30, 43). For HRVs of which full-genome sequences are known, we find that genotype 3 proteins tend to appear in reassortant strains with predominantly genotype 2 (DS-1-like) backgrounds (Fig. 1).

Of the 10 HRV reference strains, only strains Se584 and A64 encode proteins that can be classified as genotype 3 (30). Strain Se584 was isolated in 1998 from a 7-year-old child as part of a rotavirus surveillance project in the United States (18). The occurrence of this G6 serotype strain, especially in an older child, suggests that Se584 is an unusual isolate. Previous RNA hybridization studies of this virus showed that the AU-1 genogroup probes annealed to three Se584 gene segments and that no gene segments were recognized by the Wa or DS-1 probe (18). Our sequencing results contradict these RNA hybridization data; we found that Se584 encodes six genotype 2 proteins (VP1, VP2, VP3, VP6, NSP2, and NSP4), one genotype 1 protein (NSP3), and two genotype 3 proteins (NSP1 and NSP5) (Fig. 1). The reason for the lack of detectable hybridization of Se584 gene segments with the Wa or DS-1 probe in the previous study is unknown.

Our sequencing results show that strain A64 is similar to Se584 and encodes six genotype 2 proteins (VP1, VP2, VP3, VP6, NSP2, and NSP4) and two genotype 3 proteins (NSP1 and NSP5) (Fig. 1). However, while Se584 possesses a genotype 1 NSP3, the A64 NSP3 protein is not phylogenetically related to any HRV but instead seems related to an animal rotavirus (i.e., the bovine-like genotype 6) (30) (Fig. 1). Strain A64 is an unusual HRV in that it was isolated from an immunocompromised child (20) and therefore grew under conditions with atypical selective pressures. In addition to being a reassortant, this virus contains rearrangements in genes 7, 10, and 11 that stem from head-to-tail sequence duplications (2, 20). As shown in Fig. 2, all three sequence duplications initiate downstream of the ORF, thereby leaving genes 7, 10, and 11 capable of encoding full-length proteins (NSP3, NSP4, and NSP5/6, respectively). The sequence duplication in gene 11 introduces a second ORF for NSP6 in the viral RNA; yet, given its downstream position, it is not clear whether this ORF is capable of being translated (Fig. 2). Our description of the duplication of the A64 gene 10 is in agreement with that of a previous report (20). For A64 genes 7 and 11, this is the first description of the sequence duplications.

Strain L26 also represents an intergenogroup reassortant, in this case formed by genetic exchange of genes from viruses belonging to the Wa and DS-1 genogroups. The L26 strain is identified as a member of the DS-1 genogroup, since seven of its genes encode genotype 2 proteins, with two encoding genotype 1 proteins (NSP2 and NSP5) (Fig. 1). Originally isolated from a sick infant in the Philippines in 1987, L26 is a representative of the globally emerging G12 serotype (46). This strain has a long electropherotype but shows VP2 and VP6 SG-I specificities, an unusual combination for a DS-1 genogroup strain.

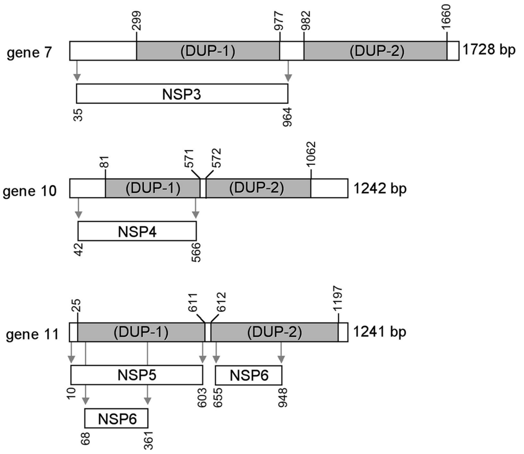

FIG. 2. Schematic of intragenic sequence rearrangements for A64 genes 7, 10, and 11. Each aberrant RNA segment contains a single head-to-tail sequence duplication (DUP-1 or DUP-2). The duplication initiates downstream of the ORF for each gene, thereby allowing A64 to express full-length NSP3, NSP4, and NSP5/6 proteins, respectively. The gene 11 rearrangement introduces a second NSP6 ORF, one that is positioned downstream of the NSP5 ORF.

Other HRVs that are known intergenogroup reassortants include several G12P[6] strains: Matlab13-03, N26-02, RV176-00, and RV161-00 (43). Matlab13-03 is predicted to belong to the Wa genogroup but encodes a genotype 2 NSP3 (Fig. 1). Strains N26-02, RV176-00, and RV161-00 can be described as DS-1-like, because the majority of their proteins are related to this genogroup (Fig. 1). N26-02 contains a genotype 1 NSP2 and an NSP4 from an animal rotavirus (genotype 6) (30) (Fig. 1). RV176-00 and RV161-00 encode NSP4 proteins that are genotype 1 and animal-like (genotype 6), respectively (30) (Fig. 1).

The fact that the HRV reassortants described above are viable demonstrates that the proteins encoded by the reassorted genes functionally replace the proteins encoded by the parental genes. Nonetheless, it is interesting that certain combinations of genes seem to exist, even among the reassortant strains. For example, the genes encoding VP1, VP2, VP3, and VP6 for each individual strain invariably belong to the same genotype. Additionally, we found that most of the reassortment events were associated with serotypes that are rarely seen in humans or that otherwise represented atypical infections (e.g., immunocompromised child or gastroenteritis in a 7-year-old) and that the predominant HRV serotypes (G1 to G4) showed no evidence of genetic exchange. Thus, these observations raise several important questions regarding possible intrinsic selection pressures influencing rotavirus diversity. Do rotaviruses have preferred gene constellations? Can proteins of different genotypes functionally substitute for each other in all cases? What are the precise amino acid changes that determine whether a protein belongs to genotype 1, 2, or 3? Do these changes cluster at sites of viral protein-protein interactions?

Correlating genotype-specific changes with protein interaction sites. To characterize the level of variation among HRV proteins belonging to genotype 1, 2, or 3, we first calculated the average intergenotype and intragenotype percent identities. In

TABLE 3. Intragenotype and intergenotype percent identities

Protein	% Identity (avg ± SD)[a] for genotypes:					
	1 vs 1	2 vs 2	3 vs 3	1 vs 2	1 vs 3	2 vs 3
VP1	98.2 ± 1.1	97.9 ± 0.9	98.3*	89.9 ± 0.4	91.3 ± 0.3	94.8 ± 0.3
VP2	97.1 ± 1.0	97.7 ± 1.8	98.8*	89.1 ± 0.8	91.5 ± 0.6	93.8 ± 0.4

[a] *, single value; no standard deviation given.

this analysis, we utilized amino acid sequence information for the 25 HRVs for which full-genome sequences are available. We note that, due to the lack of availability of genotype 3 sequences, we are more confident regarding changes differentiating genotype 1 and 2 proteins. As shown in Table 3, proteins belonging to the same genotype (excluding NSP1) have a high degree of sequence identity (93.2 to 98.8%). In contrast, the sequence identity of proteins belonging to different genotypes is at least 5% lower. Thus, on average, proteins of different genotypes will differ by 5 or more amino acids per 100 from proteins of the same genotype, suggesting a greater evolutionary distance between genotypes. While the amino acid identities for NSP1 proteins of the same genotype ranged from 88.1 to 96.6%, the identities for those of different genotypes were substantially lower (57.6 to 68.9%) (Table 3). These data indicate that the evolutionary distance between NSP1 proteins of different genotypes vastly exceeds that of the other viral proteins analyzed (see below). To identify the precise amino acid residues that distinguish proteins from genotypes 1, 2, and 3, amino acid alignments were constructed (see Fig. S1 and Table S1 in the supplemental material). Residues in the alignments that differed depending on the genotype of the protein (vis-à-vis genotype-specific differences) were identified and mapped to defined regions or known structural or functional domains (Fig. 3). We found that for some of the proteins, genotype-specific changes often clustered in sites of known viral protein-protein interactions.

Interactions among VP1, VP2, VP3, and VP6. Proteins constituting the inner layers of the rotavirus virion (VP1, VP2, VP3, and VP6) segregate with a single genotype for each of the HRVs, suggesting that they are genetically linked (Fig. 1). Because these proteins are known to interact with each other, we hypothesize that the linkage is a reflection of amino acid changes driving more favorable intragenotype interactions. The core lattice protein (VP2) engages both the viral RNA-dependent RNA polymerase (VP1) and the RNA capping enzyme (VP3) via its internally located N-terminal domain (52). The interaction between the VP2 N terminus and VP1/VP3 is thought to be critical during rotavirus RNA synthesis (viral genome replication and transcription) (38). Additionally, the outer surface of the VP2 shell interacts with VP6 during the early stages of virion morphogenesis (12). The VP2-VP6 interaction is important for the formation of double-layered particles (DLPs) and also influences the transcriptional activity of the particle (12). The outer surface of the VP2 shell domain, which is accessible to interactions with VP6, exhibits 27 amino acid differences between genotypes 1 and 2 (32) (Fig. 3). However, we found that most of the genotype-specific differences in VP2 map to the N terminus of the protein and include dramatic sequence variations and insertions/deletions, which are predicted to influence VP1/VP3 binding (32) (see Fig. S2 in the supplemental material). For the viral polymerase VP1, we identified 66 amino acids that differ between genotypes 1 and 2 (Fig. 3). Although the changes are distributed throughout the enzyme, the bulk of them are surface exposed and concentrate at the N- and C-terminal domains and the finger subdomain; in contrast, the predicted catalytic domain of the VP1 is quite conserved (26a) (Fig. 3). To our surprise, VP3, the RNA methyltransferase/guanylyltransferase, shows more genotype-specific amino acid differences than any other inner capsid protein. We found 71 changes between genotypes 1 and 2 and 22 changes among genotypes 1, 2, and 3, many of which clustered in the central region and C terminus of the protein (Fig. 3). Based on what is seen for VP1, we predict that the currently undefined VP3 catalytic sites might be located in the more conserved regions of the protein. The regions of VP1 and VP3 that mediate interactions with each other and with the VP2 N terminus are unknown. It is possible that the identified genotype-specific changes could be sites of VP1/VP2/VP3 interactions.

Interactions among VP2, VP6, VP7, and VP4. Our sequence alignments indicate that VP6 contains relatively few genotype-specific amino acid differences (see Fig. S1 in the supplemental material). Those that are present tend to cluster toward the termini of the protein, with many in or close to known VP2 interactive domains (4) (Fig. 3). Mapping these differences onto the atomic structure of VP6 indicates that the majority of them (18 out of 23 amino acids) are surface exposed and that many are situated in domain B at the base of the VP6 trimer and near the VP2 contact site (Fig. 4). The placement of these residues raises the possibility that genotype-specific changes in VP6 could influence (i) the assembly of the VP6 protein layer onto VP2, (ii) the stability of the DLP, or (iii) the transcriptional activity of VP1 (4). VP6 also engages the outer capsid proteins VP7 and VP4 during formation of infectious triple-layered particles (12). The sites on VP6 where VP7 and VP4 bind have been described previously and can be visualized on the atomic structure of the trimer (27) (Fig. 4). VP6 contains several genotype-specific changes near the VP7-binding site. Interestingly, several of these residues comprise the VP6 SG-

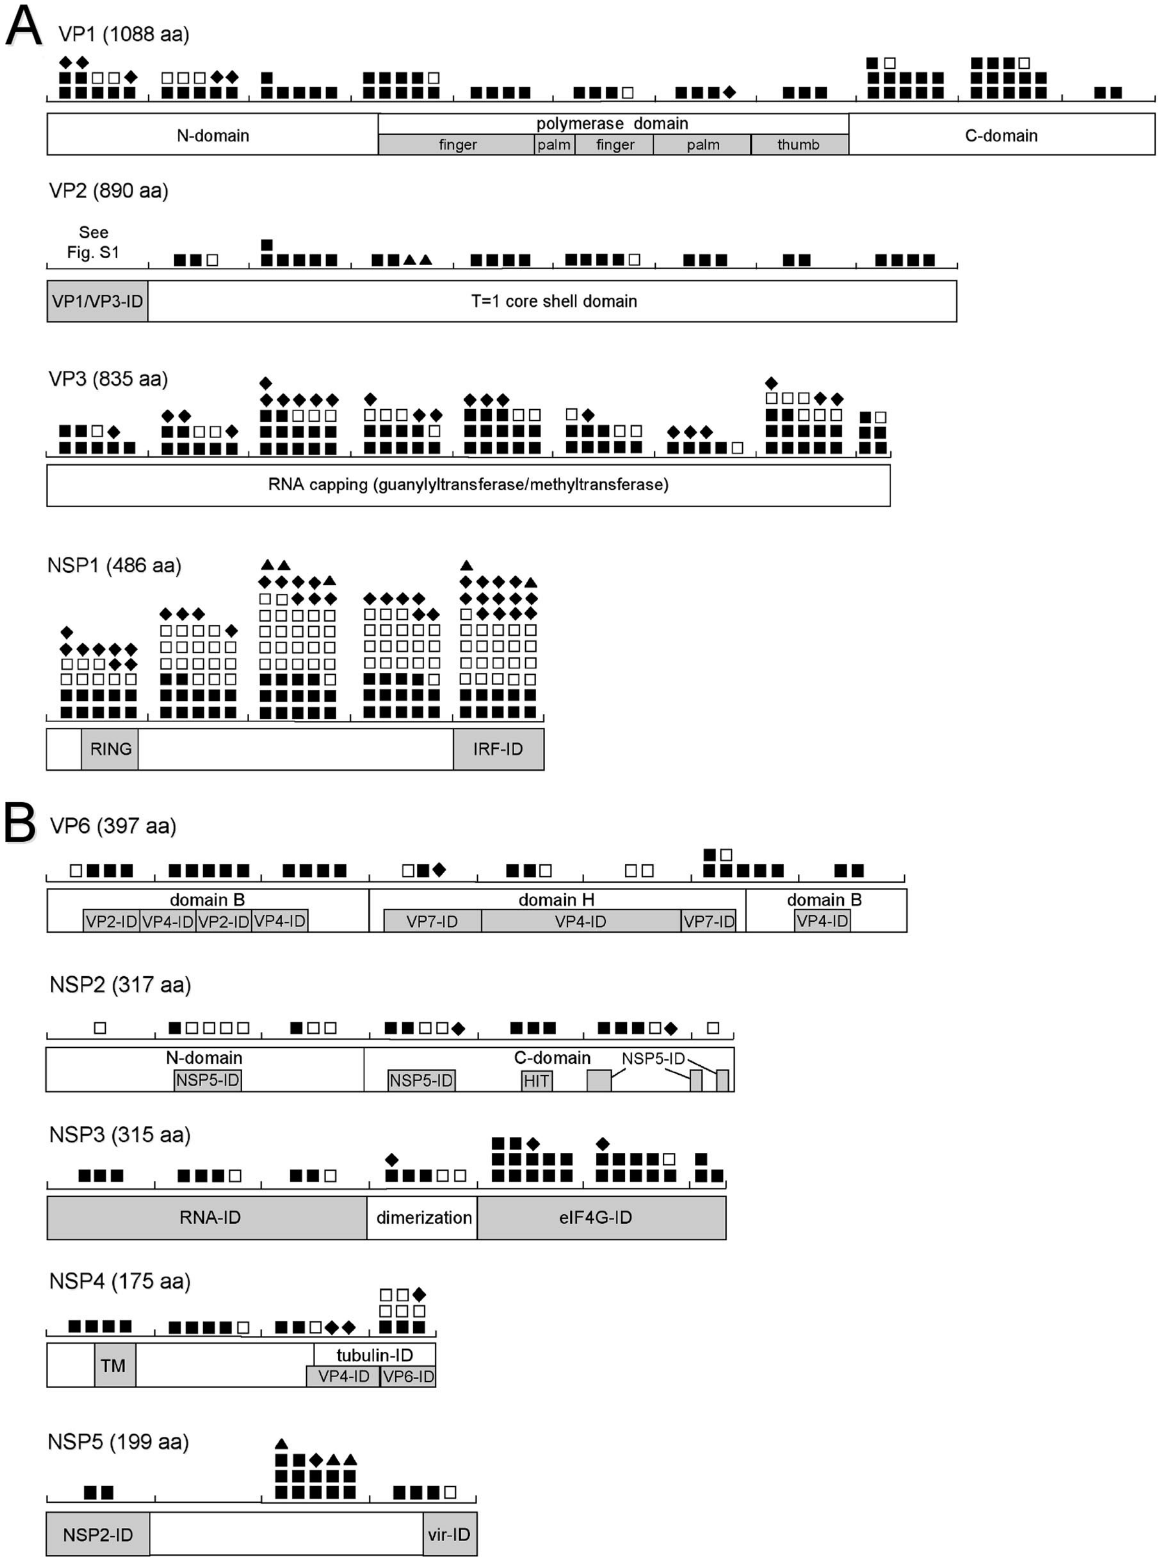

FIG. 3. Locations of genotype-specific changes in rotavirus proteins. Amino acid alignments of proteins encoded by HRVs with fully sequenced genomes were produced using MacVector 8.1.2 (see Fig. S1 in the supplemental material). From these alignments, residues that distinguished each of the three genotypes were identified. Such genotype-specific changes are indicated using symbols. Residues that are conserved among but differ between genotypes 1 and 2 are shown as black squares. Residues unique to genotype 3 proteins and not seen in genotype 1 or 2 are indicated as white squares. Residues that showed specific changes among genotypes 1, 2, and 3 are illustrated as black diamonds. Residues present in one genotype but not others (i.e., deletions) are indicated as black triangles. The amino acids identified in this analysis are presented in Table S1 in the supplemental material. For mapping purposes, the residues were then grouped into intervals of either (A) 100 amino acids (aa) (for VP1, VP2,

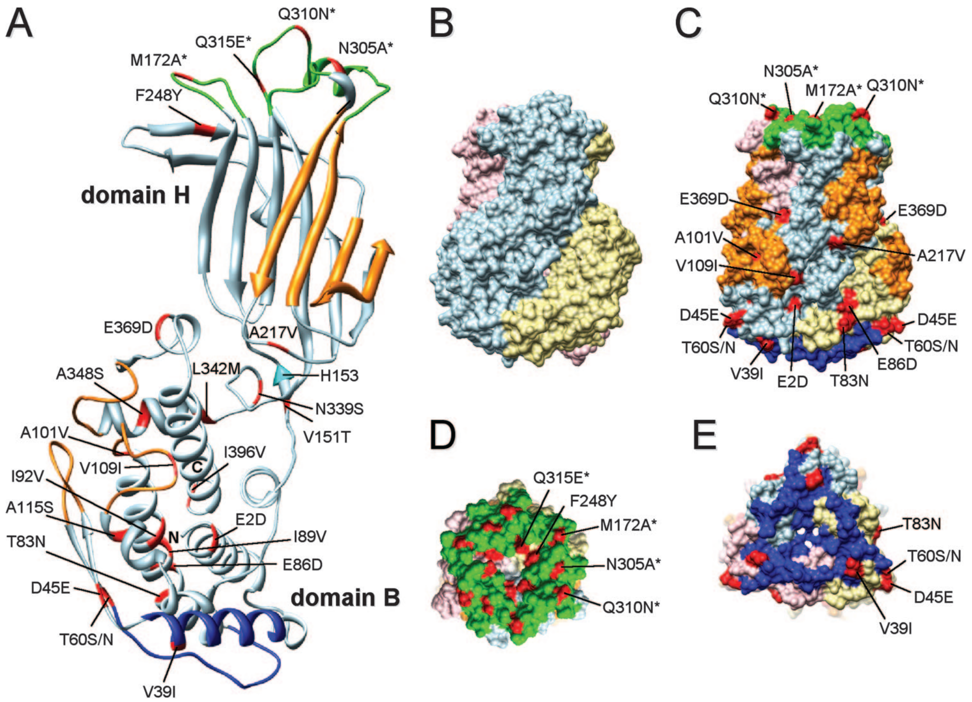

FIG. 4. Mapping genotype-specific differences on the atomic structure of VP6. (A) Ribbon diagram illustrating domain H (residues 151 to 331) and domain B (residues 1 to 150 and 331 to 397) of VP6 (bovine strain RF) (27). Regions of VP6 interfacing with VP2 (blue), VP4 (gold), and VP7 (green) are indicated, as are the locations of the N and C termini and the zinc-coordinating residue (cyan, H153). Amino acids differing between genotype 1 and 2 VP6 proteins are shown in red and are labeled. The genotype-specific residues in the VP7 interface region that define VP6 SG specificity are labeled with asterisks: SG-I (A172 and A305) and SG-II (M172, N305, Q310, and Q315) (17). (B) Surface side-view representation of the VP6 trimer, with monomers colored in light blue, pink, and yellow. (C) VP6 trimer as shown in panel B, with VP2, VP4, and VP7 interface regions and residues differing between genotypes 1 and 2 colored as described for panel A. (D and E) Top and bottom views, respectively, of the trimer shown in panel C.

specific epitopes (Fig. 4). In contrast, the site on VP6 where VP4 binds is quite conserved, and the β-roll of domain H does not show any differences between genotypes 1 and 2. Although genes encoding VP6, VP7, and VP4 of HRVs are suggested to reassort freely and independently in nature, some types of outer capsid proteins tend to appear together more frequently. For instance, genotype 2 VP6 proteins tend to associate most frequently with G2 VP7 and P[4] VP4 proteins. Preferential binding among these capsid proteins could influence (i) assembly of infectious virions, (ii) particle stability in nature, or (iii) efficiency of disassembly following entry into a host cell. Therefore, interactions between the outermost capsid proteins might be subjected to intrinsic selection pressures related to favorable interactions as well.

Interactions between VP6 and NSP4. In addition to binding to rotavirus structural proteins, VP6 engages the transmembrane glycoprotein (NSP4) during virion assembly. This interaction recruits newly formed DLPs into the endoplasmic reticulum, where, through a budding process, the outer capsid shell of the virion is formed (12). A previous study has provided evidence of a genetic linkage between VP6 and NSP4 (21). Specifically, HRVs exhibiting VP6 SG-II specificities (genotype 1) have proteins classified as NSP4B (genotype 1), whereas those bearing VP6 SG-I epitopes (genotype 2) encode NSP4A or NSP4C (genotype 2 or 3, respectively) (21). The results presented in this report are in agreement with this finding, as only three HRVs (N26-02, RV176-00, and RV161-00) for which sequences are available have VP6 and NSP4 proteins belonging to different genotypes (Fig. 1). Furthermore, while NSP4 contains very few genotype-specific amino acid differences, the changes cluster in the C terminus of the protein (Fig. 3). This observation is intriguing, as the C-terminal region of NSP4 is involved in interactions with VP6 (1). Thus, the genotype-specific amino acid variations may be connected to the genetic linkage noted for the VP6 and NSP4 proteins. Unfortunately, no information on the location of the NSP4-binding site on the VP6 trimer exists, but we expect the distal portion of the trimer to be the most likely site (Fig. 4).

VP3, and NSP1) or (B) 50 aa (for VP6, NSP2, NSP3, NSP4, and NSP5), spanning the length of the protein. The number of residues in each classification group per interval is plotted above the protein. Locations of key functional and structural domains are approximated. The genotype-specific changes for the VP2 N terminus are presented in Fig. S2 in the supplemental material. The NSP5 interactive domain (ID) on NSP2 was determined based on reference 22 and overlaps the RNA ID. IRF, interferon regulatory factor; HIT, histidine triad; TM, transmembrane domain; vir, viroplasm.

Nonetheless, NSP4 is a multifunctional protein that interacts not only with VP6 but also with VP4 and host cell membranes and proteins (e.g., tubulin) during viral replication. Aside from promoting rotavirus maturation, NSP4 functions as a viral enterotoxin that induces diarrhea through fluid loss triggered by intracellular calcium mobilization and chloride secretion (12). Thus, the pressures influencing the genetic diversity of NSP4 are not merely limited to viral protein interactions.

NSP2-NSP5 interactions and analysis of the NSP6 ORF. During replication inside a host cell, the nonstructural proteins NSP2 and NSP5 interact with each other to mediate the formation of viroplasms, which serve as sites of viral RNA synthesis and early virion morphogenesis (47). The RNA-binding protein NSP2 exists as a doughnut-shaped octamer that is formed by the interaction of two tetramers stacked tail to tail (22). Extending diagonally across the NSP2 octamer are four highly basic grooves; these represent the sites of interaction with NSP5 and single-stranded RNA (22). In addition to binding NSP5 and RNA, NSP2 is suggested to interact with one or more core proteins (e.g., VP1, VP2); yet, the binding sites for these proteins on NSP2 have not been determined (47). NSP2 and NSP5 are remarkably conserved among genotypes 1, 2, and 3, and nearly all of the genotype-specific changes for both of these proteins lie just outside of known interaction sites (Fig. 3). This observation is interesting in light of the fact that the NSP2- and NSP5-encoding genes seem to reassort more freely in the HRVs than do genes encoding the inner capsid proteins (Fig. 1). The conserved nature of the NSP2 and NSP5 interaction sites might allow these two proteins to function in a genotype-independent manner. In other words, NSP2 and NSP5 proteins from different genotypes (or even from different species) can functionally substitute for each other quite easily. For the phosphoprotein NSP5, the majority of the genotype-specific changes were noted to occur in the C-terminal half of the protein; the importance of this region is not known, but it might represent the binding site for cellular protein kinases (Fig. 3).

We should point out that, for many HRVs, the NSP5-coding gene (gene 11) has an alternative ORF that encodes a putative nonstructural protein (NSP6) (Fig. 1; also see Fig. S3 in the supplemental material). The existence of NSP6 in cells infected with HRVs has not been fully demonstrated. However, in studies using the simian strain SA11, NSP6 was detected using specific antisera and was shown to colocalize with NSP2 and NSP5 in viroplasms (33). The lengths of the NSP6 ORF sequences vary quite dramatically for the 25 HRVs analyzed in this study; yet, such variation has been noted for many animal rotavirus strains (33). Five HRVs (D, P, WI61, AU-1, and N26-02) show NSP6 ORFs that are truncated compared with that of SA11, while two of them (Se584 and A64) show extended NSP6 ORFs (Fig. 1; also see Fig. S3 in the supplemental material). We found no correlation between NSP6 ORF length and genotype/genogroup specificity. Future studies are needed to determine whether these HRVs truly express the proposed NSP6 proteins.

NSP1 and NSP3 interactions with host cells. The rotavirus nonstructural proteins NSP1 and NSP3 are unique in that they interact extensively with host cell factors but are not known to bind to any other viral proteins and are nonessential for replication in cell culture. As such, one might expect that NSP1 and NSP3 are subject to extrinsic selection pressures and should show patterns of evolution that differ from those of the other viral proteins. Our sequencing analysis shows that HRV NSP1 and NSP3 proteins can still be assigned into genotype 1, 2, or 3 but that the genes encoding these proteins tend to reassort more freely than those encoding the inner capsid proteins (Fig. 1). Additionally, the percent identity between genotypes 1 and 2 for these proteins is lower than that for any of the others, being 68.9% and 82.0% for NSP1 and NSP3, respectively, suggesting that these proteins are quite divergent (Table 3). NSP1 plays an important role in antagonizing the host cell innate immune response by inducing the proteosome-mediated degradation of transcription factors involved in interferon production (interferon regulatory factors) (3). Extensive genotype-specific changes for NSP1 are seen throughout the entire protein but are even more exaggerated in the C-terminal half (Fig. 3). A region within the C terminus of NSP1 is thought to be important for binding to interferon regulatory factor proteins (15). In contrast, the putative RING domain of NSP1, which contains a motif recognized in many E3 ubiquitin ligases, is quite conserved (Fig. 3). NSP3 is involved in abrogating host cell protein synthesis during infection and is known to interact with viral RNA and components of the cellular translation machinery (10, 40, 41). NSP3 is much more conserved than NSP1 but has genotype-specific changes clustering in its C terminus, a region important for interactions with eIF4G (eukaryotic initiation factor 4G) (Fig. 3). The reason for genotype-specific variation in NSP1 and NSP3 is not known, but it might reveal that these proteins participate in as-yet-unidentified interactions with other viral proteins.

In summary, the results presented in this report provide detailed information regarding the full-genome sequences of 10 commonly used HRV strains (D, DS-1, P, ST3, IAL28, Se584, 69M, WI61, A64, and L26). By utilizing and expanding upon the classification system of Matthijnssens et al. (30), we present evidence for the existence of preferred HRV gene constellations. Several previous reports have provided data to suggest that not all HRV genes reassort randomly; the existence of HRV genogroups is the strongest evidence in favor of this argument (9, 21, 34, 35, 49). Still, this study is the first to combine sequence analyses with structural and functional data to (i) gain insight into the normal variation within and between HRV genogroup proteins (i.e., genotypes) and (ii) provide a molecular explanation for why preferred gene constellations are maintained. Our results are consistent with the idea that genetic linkages are, at least in part, a result of intrinsic selection pressures on viral proteins. Nonetheless, we cannot rule out the possibility that interactions among RNA segments during gene assortment and packaging influence the constellations. It is important to note that intragenogroup reassortant viruses that break seemingly tight genetic linkages (for example, between VP2 and VP6) can be created in the laboratory, demonstrating that the preferences for intragenotypic protein interactions are subtle (data not shown). However, we predict that such reassortants, albeit viable, have decreased evolutionary fitness compared to that of parental strains and would be selected against in the context of infection in the human population. Without a doubt, further epidemiologic studies are required to examine if and how identified genotype-specific differences correlate with biological functions. We expect the results presented here to provide a scientific platform for such studies that will reveal the true dynamics of group A rotavirus evolution and diversity.

ACKNOWLEDGMENTS

We express our appreciation to Taka Hoshino for generously providing the HRVs used in this study and to Al Kapikian and Jelle Matthijnssens for insightful comments and critical readings of the manuscript.

Abstract

Multiple sclerosis (MS) is chronic, inflammatory disease of the central nervous system that mainly affects young adults and is characterized with dissemination of demyelinating lesions in time and space. It is well known that MS is very heterogeneous disease, so biomarkers that would reliably determine disease course, outcome or treatment response in early stages of the disease (preferentially clinically isolated syndrome) are desperately needed. Genome-wide expression analysis represents the profile or imprint of all genes in a certain tissue or cell population in certain time point. Therefore, as human genome is entirely known, it is possible to analyze any given human gene in any given context. This review will discuss results and possible applications of gnome-wide expression studies in brain tissue and blood samples of MS patients.

Key words: Multiple sclerosis, biomarkers, genomics, microarrays

Introduction

Multiple sclerosis (MS) is chronic, inflammatory disease of the central nervous system (CNS) that mainly affects young adults and is characterized with demyelination. Although MS is pathologically and clinically heterogeneous disease, in 85% of patients it starts with acute or subacute episode of neurological dysfunction attributable to one or more foci of demyelination, which is called clinically isolated syndrome (CIS). In 21% of patients, CIS manifests as optic neuritis, 46% myelopathy, 10% with brainstem symptoms and in 23% with multifocal symptoms.[1] One of the main characteristics of MS is high heterogeneity in final outcome between patients, with benign or even asymptomatic disease on one end and highly aggressive, malignant disease on the other end of the spectrum. Therefore biomarkers that would reliably determine disease course, outcome or treatment response in early stages of the disease (preferentially CIS) are desperately needed.

Biomarkers

Biomarkers are very important indicators of normal or abnormal biological processes. By definition, biological markers or biomarkers are characteristics that can be objectively measured, and serve as indicators of normal biological process, pathological process or pharmacological response to therapeutic intervention.[2] Potential implications for biomarkers are numerable, they can be used in disease diagnosis and monitoring and determining early efficiency of treatment. As well, they are invaluable in early disease detection, staging and prognosis.

MS is heterogeneous disease in rate of progression, clinical symptoms, specificity of immune response and pathology of MS lesions, so it is to be expected that certain biomarker will reflect just one of many pathogenetic mechanisms involved.[3] Therefore patient stratification will be possible only with defined group of biomarkers so relative contribution of each of different pathogenetic mechanisms can be determined.[4] It is also important that every biomarker is validated in different, independent cohorts in prospective multicentric studies.

Validation criteria for each biomarker are defined according to the purpose for which the biomarker in question is created and should be standardized in different cohorts with following goals:[4]

1) Clinical relevance: biomarker has ability to follow changes in the pathological process and/or therapeutic intervention in relatively short period of time
2) Sensitivity: ability that the biomarker can be measured with precisely enough and that change of biomarker reflects the change of clinical endpoint
3) Specificity: ability of biomarker to identify persons with certain disease or response to certain therapeutic intervention
4) Probability of falsely positive and falsely negative cases: defined as situation in which change of the biomarker does not reflect change of the certain clinical endpoint
5) Accuracy, precision, reproducibility and variability of the laboratory test which measures the biomarker

Currently there is no MS biomarker that fulfills all of the above mentioned criteria.[5]

Genomics

The development of genomics has for the first time made possible to overcome many of above mentioned problems in development of MS biomarkers. With this method it is possible to determine the profile or imprint of all genes in certain tissue or cell population in certain time point. As human genome is entirely known, it is possible to analyze any given human gene in any given context, so it is possible to understand complex molecular interactions, discover biomarkers that correlate well with clinical signs and discover new therapeutic possibilities.[6] Genomic analysis is performed with microarrays that contain known oligonucleotides of very high density, attached to surface in a specific order of very high density. DNA microarrays can be divided in two groups according to DNA type: oligo microarrays contain synthesized oligonucleotids, while cDNA microarrays contain complementary DNA molecule cloned or amplified with PCR.[7,8] The main objection of this method is that it is not hypothesis driven. However, because genetically MS is very complex disease and there is great heterogeneity in clinical picture, genome-wide expression studies have clear advantage over conventional studies, with possibility of forming new hypotheses.[6] During the interpretation of data obtained with these studies, researcher should always bear in mind intra- and interindividual variations between patients[9]. Furthermore, there always exists a question of technical variability, namely use of different microarrays and manufacturer specific protocols, which may influence the final results of expression profiling experiments. Recent studies, such as Microarray Quality Control project have provided some reassurance about the reproducibility of contemporary microarray platforms, showing an average 89% overlap in expression profiles generated between sites using the same microarray platforms and 74% overlap across platforms from different manufacturers.[10] Alternatively, using two or more microarray platforms in analysis of the same samples and selecting the most reproducibly differentially expressed genes as biomarkers, could provide a way to reduce the influence of inter-platform technical variability on the process of biomarker selection. Finally, proper selection of statistical methods used is crucial, as it can also be a source of bias in the procedure of new biomarker selection.

Recently guidelines have been set out for improvement of reliability of microarray results:[6]

1. Microarray results should be confirmed with alternative methods (real time PCR). However shortage of confirmatory tests does not reduce the importance of microarray results if the microarray experiment is of sufficient quality.
2. Microarray results should always be replicated in an independent cohort of patients. As an alternative one may use biostatistical methods.
3. All samples should be collected at the same time of the day, and time between sample collection and processing should be standardized.
4. If one is doing blood samples analysis, distribution of main mononuclear cell lineages should be analyzed.
5. Relapses, infections and drugs should not interfere with the results.
6. All samples should be collected by standardized method.
7. Analysis should include and dose genes which are near the cut-ff values.
8. Microarrays provide us with great amount of data, so every researcher should make a repository of all available data so the rest of scientific community can gain access to the results. Repositories like this should be in concordance with MIAME (Minimum Information About a Microarray Experiment) guidelines.[11]

What have we learned from genome-wide expression studies in brain tissue of MS patients?

The first study using gene microarrays on brain tissue of MS patients was published in 1999.[12] This study investigated expression profiles differences of more than 5000 genes between normal brain tissue and acute MS plaques and found expression differences in 62 genes, among them Duffy chemokine receptor, interferon regulatory factor-2 and TNF alpha receptor2. Following this study, many investigators used gene microarrays on brain tissue of MS patients with aim of discovery of new biomarkers[13,14], new pathophysiological mechanisms or new therapeutic targets.[9,15-22]

Most of these studies are performed on postmortem tissue, because biopsies are very rarely performed in MS patients. As degradation of RNA happens relatively quickly after death, it is necessary to process brain tissue very quickly in order to obtain RNA of high enough quality for DNA microarrays. Despite this RNA can be isolated from postmortem samples up to 20 hours after death, although short time does not guaranty RNA of high quality.[23] It should be emphasized that postmortem tissue, despite all disadvantages, is a very important source for gene microarrays, especially when investigating new pathogenetic mechanisms and discovery of new therapeutic targets.[23] It is always necessary to carefully characterize the tissue from which RNA will be isolated, immunohistochemistry with markers for demyelination, infiltration and gliosis are all required for good interpretation of results. All these tasks are almost impossible to fulfill, but they should be taken into account when analyzing the data.

In order to identify genes which are crucial in MS pathogenesis, Whitney and coworkers have compared gene expression profiles in MS lesions and brains of EAE mice with normal white matter.[12] Altogether 2798 genes were compared and one of the most important findings was that 5-lipooxigenase, a key enzyme in the biosynthesis of proinlammatory leukotrienes, is overexpressed in MS lesions and brains of EAE mice. Although this finding is not specific to

MS, it emphasizes the importance of proinflammatory activity in demyelinating process and suggests the possible role of antiiflammatory therapy in MS.

Tajouri and coworkers have compared RNA expression profiles of chronic active and acute MS lesions between themselves and in comparison with normal white matter.[15] These authors have identified 139 differentially expressed genes between MS lesion and normal tissue, 69 of them showed same direction of expression in both chronic active and acute MS lesions, while 70 genes showed different direction of expression between chronic active and acute MS lesions. This study revealed genes with already known role in MS pathogenesis like myelin basic protein, glutathione-S-transferase M1 and different growth factors. As both, chronic and acute lesion, had similar expression profiles, it has been suggested that quantitative rather than qualitative differences in gene expression, define progression from acute to chronic active MS lesion.

Further studies have confirmed differences in gene expression between chronic active and inactive MS lesions, in their edges as well as in the central parts.[16] The most differentially expressed genes were genes implicated in inflammatory response, apoptosis related and stress-induced genes. Major differences in gene expression occurred between the lesion margin and lesion centre in active lesions (57 and 69 genes differentially expressed, respectively), whereas the margins and centres of silent lesions showed markedly reduced heterogeneity (only 11 and two genes differentially expressed, respectively).[17]

Microarray analysis of MS lesions obtained at autopsy revealed increased transcripts of genes encoding inflammatory cytokines, particularly interleukin-6 and -17, interferon-gamma and associated downstream pathways. Comparison of acute lesions with inflammation versus 'silent' lesions without inflammation also revealed differentially transcribed genes.[18] Some of these differentially expressed genes were chosen as therapeutic targets in EAE model of MS, and these results have confirmed the importance of microarray analysis research.

Microarrays on autopsy samples of patients with secondary progressive MS provided molecular evidence of a continuum of dysfunctional homeostasis and inflammatory changes between lesions and normal appearing white matter (NAWM), and supported the concept of MS pathogenesis being a generalised process that involves the entire CNS.[19] When comparing gene expression in NAWM of postmortem brains of MS patients, there is increased expression of genes involved in maintenance of cellular homeostasis, and in neural protective mechanisms known to be induced upon ischemic preconditioning.[20] When comparing expression levels of 33,000 characterized genes in postmortem motor cortex from MS brains, compared with controls, 488 transcripts were found to be decreased and 67 increased. Twenty-six nuclear-encoded mitochondrial genes and the functional activities of mitochondrial respiratory chain complexes I and III were decreased in the MS motor cortex, which was specific for neurons. In addition, pre-synaptic and postsynaptic components of GABAergic neurotransmission and the density of inhibitory interneuron processes also were decreased in the MS cortex.[21] These data supports a mechanism whereby reduced ATP production in demyelinated segments of upper motor neuron axons contributes to progressive neurological disability in MS patients.

One of the advantages of microarray technology is that specific group of genes related to a specific pathway or process can be analyzed separately. In this context, a focused endothelial cell biology microarray, capable of detecting changes in expression of 113 blood/brain barrier-specific genes showed 52 differentially expressed genes in MS lesions compared to NAWM and healthy controls.[22]

What have we learned from gene expression studies on human blood samples in MS?

One of the most important factor that one should take into account when interpreting results of gene expression studies on human blood samples is great interindividual and time variation in gene expression in healthy subjects.[24,25] These variations are dependent on cell composition of the blood, sex, age and time of the day when samples are taken. The partly intrinsic variations can be caused by genotype differences, epigenetic phenomena or environmental and nutritional factors. That is why as many as possible variables should be controlled during processing of samples for microrarray studies.

On the other side, gene expression studies on human blood samples have many advantages. Blood is a very accessible sample to take so it is possible to perform analysis on larger number of patients than in studies using brain tissue. Results obtained with this method can give insight into drug efficacy much earlier, because blood is one of the first tissue with which the drug comes into touch with. However it should be kept in mind that blood also has many disadvantages, mainly because it reflects influence of other factors not pertinent to the disease process itself.[26]

There are two possible ways how to isolate RNA from blood samples. One is isolation of peripheral blood mononuclear cells (PBMC) from the whole blood by Ficoll gradient, and the other one is isolation of RNA from the whole blood with Paxgene tubes. Both procedures have their advantages and disadvantages.

Gene expression studies on human blood samples in MS have been used for diagnostic (differentiation of MS patients from healthy controls, differentiation different MS types, differentiation of treated MS patients from untreated MS patients), prognostic (differentiation of MS patients in relapse from patients in remission) and therapeutic (differentiation of treatment responders form treatment failures) purposes. One of the first studies aimed at discovering specific expression patterns in blood of patients demonstrated that cDNA microarray technology could be used to identify large-scale abnormal gene expression patterns in the peripheral blood of MS patients. This study identified 34 differentially expressed genes in patients with a relapse-remitting form of the disease when compared to healthy individuals. Significant increases were observed in molecules involved in T-cell and B-cell activation (LCK, CAMP responsive element modulator, IL-7 receptor), and degradation of extracellular matrix (MMP-19 or RASI-1), and significant decreases were observed in proteins that serve as chemokine receptors (STRL 22), are involved in apoptosis (DNA fragmentation factor-45) or in humoral immune responses (immunoglobulin heavy chain Gm marker).[27] Further to this study, Bomprezzi and collaborators identified a set of 53 genes differentially expressed in MS patients that can be used to predict the disease state in an independent test set.[13] As well the findings of this study supported the significance of autoreactive T cell activation as a primary pathophysiological event in MS. In an effort to develop a biomarker capable on not only successfully diagnosing patients with MS, but also differentiating between those experiencing a relapse from patients in remission, Achiron and coworkers identified 721 genes involved in activation of T-cells, epitope spreading and evasion of immune regulation in patients with acute MS relapse, when compared to MS patients in remission.[28] As well, this study broadened the number of differentiating genes between MS and healthy controles to 1,109 (589 overexpressed and 520 underexpressed) mainly involved in T-cell expansion and activation, inflammatory stimuli (cytokines and integrins), epitope spreading, and survival advantage leading to aberrant apoptosis.

Much larger number of studies tried to investigate changes in peripheral blood expression in response to immunomodulatory therapy. A study performed in patients receiving interferon beta therapy discovered that its action is not purely anti-inflammatory[29], and further studies identified 21 genes differentially expresses in blood of MS patients treated with interferon beta after 3 and 6 months of therapy. Out of the 21 differentially expressed genes, 9 possessed interferon responsive promoters. No significant change in expression of Th1 or Th2 related genes was observed.[30] These studies showed the complexity of expression changes in response to interferon therapy, and indicated the effect it exerts on cell migration, matrix degradation, proliferation, cell cycle control, differentiation, cell processing and presentation, apoptosis and cytokine and chemokine regulation. Trying to identify genes which could predict a favorable response to interferon therapy, a group of authors showed that interleukin 8 might be useful in predicting which patients will show a positive response.[31] These studies also showed that interferon beta induces expression of genes in a selective and time dependent manner, indicating its possible role in monitoring response to therapy.[32] This is especially true for genes involved in antiviral response, which are induced 1-4 hours following interferon beta administration. Similar expression pattern can be observed in genes involved in interferon beta signaling and lymphocyte activation.

Meta-analysis of expression profiling studies conducted using blood samples of patients with MS indicated 15 potential biomarkers which are expressed during the entire course of beta interferon treatment and which can serve as biomarkers of response to therapy. These include EIF2AK2, IFI6, IFI44, IFI44L, IFIH1, IFIT1, IFIT2, IFIT3, ISG15, MX1, OASL, RSAD2, SN, XAF1 and transcript represented by the Affymetrix probe 238704_at.[33] These biomarkers were all formerly identified as being indicative for IFNB activity.

More recently, it has been shown that after second day, one month, 12 months and 24 months of initiation of interferon therapy there are 42, 175, 103 and 108 differentially expressed genes, respectively. *MS4A1* (CD20), a known target of B-cell depletion therapy, was significantly downregulated after one month and *CMPK2*, *FCER1A*, and *FFAR2* appeared as hitherto unrecognized multiple sclerosis treatment-related differentially expressed genes that were consistently modulated over time.[34]

Another drug approved for RRMS treatment is glatiramer actetate (GA). Gene expression studies on human blood samples have shown that GA alters expression of 480 genes within 3 months of treatment; 262 genes were up-regulated, and 218 genes were down-regulated. The main convergent mechanisms of GA effects were related to antigen-activated apoptosis, inflammation, adhesion, and MHC class-I antigen presentation.[35]

Conclusion

So far, microarrays performed on brain tissue of MS patient provided us with important findings related to MS pathogenesis. Identification of endogenous protective mechanisms in MS brains can lead to development of new drugs which could slow the progression of disability.[23]

The expression signature of MS as detected in PBMC can be used in assessment and monitoring MS patients, discovery of new pathogenetic mechanisms and monitoring of response to treatment. However one has to bare in mind, that in a complex disease like MS both multiple interactions of different components of the immune system *in vivo*, and the complexity of the intracellular pathways must be considered in the interpretation of microarray experiments.[36]

In both cases, future studies with larger number of well defined patients will give us a better insight in molecular basis of heterogeneity of MS.

Chronic Viral Hepatitis and the Human Genome

Chloe L. Thio,[1] David L. Thomas,[1] and Mary Carrington[2]

Recently, molecular genetic tools have increased our ability to discover variations (polymorphisms) in the human genome and to correlate them with disease. Although still a discipline in its infancy, infectious disease outcomes may also be predetermined by genetic polymorphisms because differences in a host's susceptibility to infection and severity of disease cannot solely be attributed to the virulence of an organism. The earliest and best-known example of such genetically determined factors is malaria. Africans with Hemoglobin S are protected from severe infection with *Plasmodium falciparum* because the parasite cannot survive in the sickled cell.[1] Subsequently, tuberculosis and human immunodeficiency virus (HIV) outcomes have been correlated with polymorphisms in various genes.

Genetic associations may provide clues to fundamental questions about the pathogenesis of an organism and lead to new therapeutic avenues. For chronic viral hepatitis, this approach may help determine the basis for viral persistence and development of end-stage complications like cirrhosis or hepatocellular carcinoma. Initial genetic studies of viral hepatitis focused on human leukocyte antigen (HLA) associations. Much of this early literature is conflicting, possibly because of differences in study design and subjects, as well as failure to account for nonrandom association of genes (linkage disequilibrium). Currently, by exploiting the recent advances in molecular technology, such as genome-wide scans and large-scale polymorphism screening, investigators can screen a large number of subjects and identify multiple associated alleles. In the future, such studies may provide clues to help predict the natural outcome of a viral hepatitis infection or the response to therapy. This review provides some background into the molecular techniques used for genetic studies and summarizes the existing literature of host genetics with hepatitis B (HBV) and hepatitis C viruses (HCV).

CANDIDATE GENES

A candidate gene encodes for products that are hypothesized to influence the susceptibility to, or the course of, a particular disease. To determine if these genes contribute to the disease phenotype, its polymorphisms are examined in disease association or family studies. A candidate gene may be proposed if biological information suggests that its products may influence the known pathogenesis. Such an approach is illustrated by an example from the HIV literature. The chemokine receptor CCR5 was shown to behave as a coreceptor for HIV-1 entry into the CD4 cell,[2] so its gene was screened for polymorphisms. Individuals homozygous for a 32 base-pair (bp) deletion (CCR5Δ32) in this gene are resistant to HIV-1 infection, and those heterozygous for this deletion have delayed progression to AIDS.[3]

Other methods for proposing candidate genes include studying homologues of genes identified in an animal model or examining a gene implicated in a similar disease. For example, the gene NRAMP1 was examined for tuberculosis susceptibility because it is the human homologue of the mouse gene that is partly responsible for susceptibility to intracellular pathogens.[4] The hemochromatosis gene, HFE, is being investigated with viral hepatitis outcomes because iron has been implicated in viral hepatitis pathogenesis.[5] Limitations to these methods include prior identification of a gene, its polymorphisms, and its functional significance.

Another approach to identify candidate genes without these limitations is with a genome-wide scan, which uses densely distributed markers, either microsatellites or single nucleotide polymorphisms, to identify areas of interest in the genome. Distortions in the frequencies of these markers are compared between a cohort of patients with a specified outcome and those without the outcome or in a group of families with the disease phenotype.[6,7] If a disease-associated polymorphism and a marker are linked, then the marker will be found significantly more frequently in those with the disease.

Microsatellites are tandem repeats of two to four base pairs occurring approximately every 30 kilobases in the eukaryotic genome. In a study of five diseases (insulin-dependent diabetes mellitus, narcolepsy, uveitis, C2 deficiency, and multiple sclerosis) with known HLA associations, the microsatellites in closest proximity to the disease gene were significantly associated.[8] Thus, in diseases without previously recognized genetic associations, distortions in frequencies of microsatellite markers can focus the search for the associated gene.

Single nucleotide polymorphisms are polymorphisms produced by a single base change. These may be superior to microsatellites because they do not mutate as frequently, are more abundant, and are easier to analyze. If a large area of the genome is thought to be of interest, single nucleotide polymorphisms can be identified by denaturing high perfor-

mance liquid chromatography, which is based on the property that heteroduplex DNA fragments compared with homoduplexes have reduced retention time on the liquid chromatography column.[9]

Major Histocompatibility Complex. The human major histocompatibility complex is located on the short arm of chromosome 6 and encodes for several protein products involved in immune function including complement, TNF-α, and the HLA complex, whose polymorphisms are often proposed as candidate genes (Fig. 1). The HLA complex consists of class I (HLA-A, -B, and -C) and class II (HLA-DRB1, -DQA1, -DQB1, -DPA1, and -DPB1) alleles. As the primary inducer of an immune response, the HLA present foreign antigens to both the CD4+ helper T cells and the CD8+ cytolytic T cells (CTLs). Class I molecules generally present antigens that are generated endogenously, including epitopes from viruses and other intracellular pathogens. To eliminate virally-infected hepatocytes, CTLs must recognize the combination of viral epitope and a class I antigen co-expressed on the surface of the hepatocyte. Class II molecules on antigen presenting cells present extracellularly derived antigens, including viral peptides, to CD4+ T cells to stimulate cytokine release generating both humoral and cell-mediated immune responses.

The HLA genes are the most diverse in the human genome, presumably an evolutionary adaptation to immune pressure from various infectious agents. Despite their heterogeneity, the HLA genes have been extensively characterized, and large-scale typing is now feasible. Because the methodology for class II typing has advanced more rapidly than for class I, most studies to date have employed serological class I typing, which is less specific than the recently-developed molecular techniques. Serological typing is based on HLA-specific antibody binding to antigens exposed on the cell surface. Thus, polymorphisms in the unexposed peptide-binding groove, which determines the antigenic epitopes presented to T cells, often escape detection. Presently, the most accurate methods for class I typing involve some combination of PCR-SSP (polymerase chain reaction sequence-specific primers), PCR-SSO (polymerase chain reaction sequence-specific oligonucleotide), and direct sequencing. In PCR-SSP, primers are designed to amplify one or more specific alleles by PCR, and the products are separated on an agarose gel.[10] Thus, determining the presence or absence of a product uniquely identifies a large number of alleles. In PCR-SSO, genomic DNA is amplified by PCR with locus-specific primers, the products are blotted onto a membrane, and the blot is then hybridized with oligonucleotide probes specific for particular alleles.[11] Accurate methods for class II HLA typing typically involve some combination of PCR-SSCP (sequence-specific conformational polymorphism), PCR-SSO, PCR-SSP, and sequencing. SSCP is based on the property that single base changes alter the conformation of single-stranded DNA, which leads to slower migration on a nondenaturing polyacrylamide gel.[12]

METHODS FOR CANDIDATE GENE ANALYSIS

Linkage. Linkage disequilibrium refers to the nonrandom association of alleles such that a particular allelic combination occurs more often than is expected by chance. For example, HLA-A1 and HLA-B8 occur in 27.5% and 15.7% of Caucasians, respectively. Thus, they would be expected to occur together in 4.3% (27.5% × 15.7%) of Caucasians assuming random mating, but they actually are found together twofold more often (9.8%) indicating they are in linkage disequilibrium and form a haplotype.[13] In family studies, linkage analysis is useful to study genes in large pedigrees. In association based studies, a marker locus, such as a microsatellite, is linked to the disease locus and can be compared in a case-control analysis.

Interpreting results of genetic studies can be complicated by linkage disequilibrium such that the implicated gene may be linked to the true gene of interest. This molecular confounding is similar to concluding that alcohol use causes lung cancer because of its epidemiological linkage to tobacco use. Linkage disequilibrium can occur through genetic proximity or from selection pressure favoring a particular combination of alleles at two distant loci.

Family Studies. Before the technology to study candidate genes in disease association studies was available, family studies were used, and are still used, to provide the first clues to a genetic basis for an infectious disease. In family studies, individuals with a particular disease comprise the initial cohort, and their relatives are studied to determine if they also have an excess frequency of the disease in question. Through the use of segregation analysis, these studies can suggest a pattern of inheritance of the susceptibility genes. With the advent of molecular genetics technology, results from disease association studies can be combined with family studies to determine the inheritance pattern of a particular candidate gene.

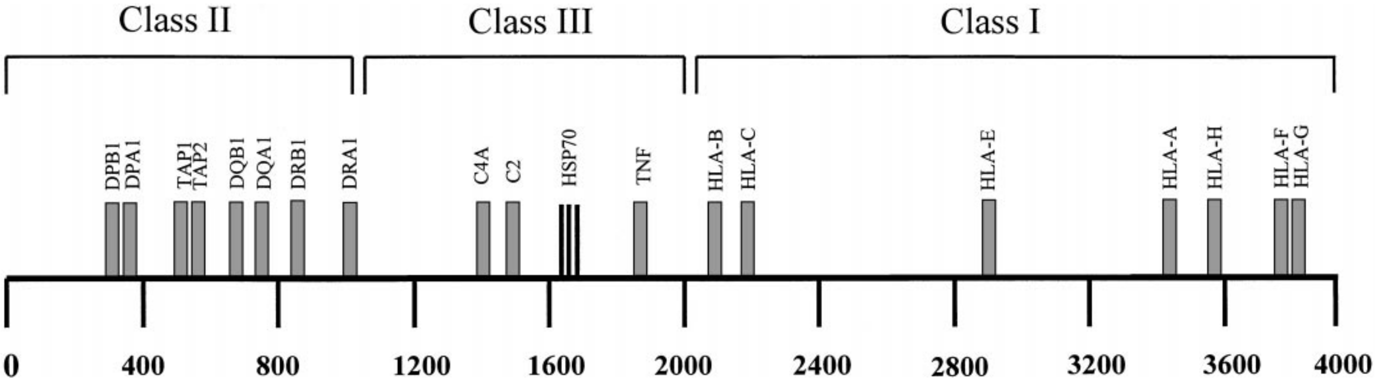

FIG. 1. The major histocompatibility complex (MHC) is located on the short arm of chromosome 6. Over 200 genes are encoded for in the MHC, many of which are involved in immune responsiveness. The relative locations of the major known genes are depicted in this schematic illustration.

In contrast to other family studies, twin and adoptee studies can separate the genetic and environmental components because monozygotic twins share 100% of genes and dizygotic twins share, on average, 50%. In general, family studies are relatively insensitive and require both uniform exposure to the infectious disease and high penetrance of the putative allele. Thus, in the majority of genetic studies of infectious diseases, a more sensitive way to detect disease-associated genes is to compare their allele frequencies between cases and controls.

Disease Association Studies. In disease association studies, a candidate gene polymorphism is studied in a group of individuals exposed to a particular infection. The frequencies of the polymorphism are then compared between those with and without a predefined study outcome. Using the example from HIV presented earlier, study outcomes with the CCR5 polymorphism included resistance versus susceptibility to infection and rapid versus slow progression to AIDS.[3] Most studies to date of HBV and HCV have employed this method of study, but difficulties involved in designing such studies include an inappropriate control group (detailed later) or a small number of study participants.[14-21]

The control group in most of the viral hepatitis studies is from the general population[22-28] or from blood or bone marrow donors,[29-31] which can lead to a misclassification bias because some of these individuals may not have been exposed to the virus. In such cases, true associations may be missed because unexposed subjects capable of becoming infected are included as controls. For studies of viral persistence, appropriate control groups are individuals that have cleared the infection and for studies of susceptibility to infection, the control group should be exposed and uninfected persons. The potential also exists for a control group to be enriched for another disease that has HLA or other genetic associations such as malaria, diabetes, HIV, etc.; thus, the associations discovered may reflect patterns with this other disease. Matching for such potential associations can eliminate this bias.

Genetic epidemiological studies require a large number of subjects to attain adequate statistical power. This problem is particularly apropos to HLA association studies because of the inordinately large number and fairly even distribution of alleles at some of these loci. As a hypothetical example, for an allele with a frequency of 10%, 307 case-control pairs are needed to have an 80% chance of detecting a twofold disease association. Most gene frequencies, especially in the HLA complex, are lower than 10%, further increasing the number of subjects required to investigate even modest disease associations.

Allele frequencies also vary between ethnic groups, so associations may only be detected in people of a particular ethnicity. The best example is the CCR5Δ32 polymorphism for HIV, which is found in Caucasians but is not detected in Africans.[32,33] Similarly, if a gene associated with viral hepatitis is limited to a particular ethnic group, then this association would not be detected in all studies; a multicohort study is ideal to examine such ethnically varied associations. For the same reason, the control population should be of the same ethnicity as the study population or alternatively, the two should be matched by race.

GENETICS AND HEPATITIS VIRUS

Hepatitis B Virus

Natural History. When hepatitis B virus (HBV) is acquired in adulthood, the majority of infections are cleared, with chronic infection occurring in 5% to 10% of cases.[34] However, 90% of childhood-acquired disease persists. In the developing world, where high endemic levels of HBV exist, acquisition usually occurs in childhood from either perinatal or horizontal (one child to another) transmission. In economically developed countries, HBV is usually acquired in adulthood via sexual transmission or injection drug use. When comparing studies of HBV and host genetics, the age-related variation in immune response may be a factor influencing the results.

Family Studies. Family studies in China provide some evidence that host genetic factors influence viral persistence, as higher concordance rates were found for HBeAg persistence in identical compared with nonidentical twins.[35] There are no family studies that have examined a genetic basis for susceptibility to HBV infection.

HLA Studies. The majority of host genetic studies with HBV have concentrated on HLA associations. Table 1 summarizes data from journal articles published between the years 1987 and 1998 reporting HLA class I and class II associations. All of these studies examined associations with persistence of HBV and a few studies additionally examined disease progression.[14,15,22-24,28-30,36-39] Seven of the twelve studies used controls who had cleared the infection,[14,15,28,29,36,37,39] and the remainder used controls from the general population. None of the seven identified associations between class I alleles and viral persistence, but only one used molecular typing.[14]

Class II associations were noted in four of the seven studies that compared viral persistence with viral clearance.[14,15,36,37] Using restriction fragment length polymorphism analysis, Thursz et al. examined a large cohort of children from The Gambia and found DRB1*1302 to be more frequent in the group that cleared the infection. The protective effect of this allele was validated in a smaller cohort of Gambian adults.[36] The cohort in both studies was a subset of a larger malaria study in which the DRB1*1302 allele was also found to be protective against severe malaria. The distribution of severe malaria cases in the persistent and self-limited HBV infections was not provided, so malaria may be a confounding factor in this study. In The Gambia, HBV is usually acquired in childhood via horizontal transmission. Because children are much more likely to become persistently infected than are adults, this association may not be generalizable to populations in which HBV is acquired in adulthood. The adults in the validation cohort probably also acquired their infection in childhood; thus a survivor bias may be present in the adult cohort. In support of this association, a separate German study designed to test the effect of DRB1*1302 in adults also suggested a protective role for this allele against viral persistence.[37]

A third study, which used SSCP and SSP, involved 31 self-limited and 60 persistent HBV infections in adult African-American injection-drug users from Baltimore, MD. This study showed the association of persistence with DQA1*0501 and DQB1*0301, which are found on a common DQA1-DQB1 haplotype. The 3 locus haplotype DQA1*0501-DQB1*0301-DRB1*1102 was also significantly associated with persistence.

TABLE 1. Summary of All Statistically Significant HLA Associations With Hepatitis B Virus Persistence

Outcome (Numbers)	Controls (Numbers)	Risk Group	Population	Alleles Associated With Outcome	Comment	Ref
Persistence (31)	Clearance (60)	Adult, injection drug users	African-Americans	DQA*0501, DQB*0301; haplotype of these 2 alleles alone and with DRB1*1102	Small numbers	14
Persistence (185 children)	Clearance (218 children)	Children (≤10 yo)	Gambians	DRB1*1302 negatively associated	1) CI-serol typing 2) Distribution of malaria cases unknown 3) Childhood acquired disease	36
(40 adults)	195 (adults)	Adults	Gambians	DRB1*1302 negatively associated		
Persistence (21)	Clearance (31)	Adults; Blood donors, Hepatitis clinic	Qatarians	DR-7 positively associated; DR-2 negatively associated	1) Serol typing 2) Small numbers 3) Most controls unexposed 4) Clearance people not HBsAg tested	15
Persistence (107) (70 tested for DRB1)	Clearance (24) & Unexposed (101)	Adults; Liver center	Germans	DRB1*1301-2 negatively associated	1) CI serol typing 2) Most controls unexposed 3) No DQA, DQB testing 4) Clearance people not HBsAg tested	37
Persistence (97)	Clearance (52) & blood and marrow donors (489)	Adults	Italians		1) Serol typing 2) Most controls unexposed 3) Clearance people not HBsAg tested	29
Persistence (80)	Clearance (157)	Adults, HD patients	88% Caucasian 12% African		1) Serol typing 2) No DQA, DQB 3) Controls not HBsAg tested	28
Persistence and disease severity (22)	Blood donors (80)	Adults; Liver clinic	Caucasian		1) Controls unexposed 2) Small numbers 3) 17 DR3 and DR4 tested	30
Persistence (51)	Unspecified (97)	Adults	Latin Americans	B35 positively associated	1) Serol typing 2) DQA, DQB not tested 3) Controls unexposed 4) Small numbers	38
Disease severity and persistence (79-37 with CAH)	Clearance (117); random blood donors (200)	Adults	Dutch	DQw1 (↓ in CAH)	Serol typing	39
Disease severity, persistence (95 HBsAg healthy carriers, 210 chronic liver disease)	Random (253) (182-DR typing)	Adults	Taiwanese		1) Serol typing 2) Controls unexposed 3) DQA, DQB not tested	22
Persistence (78)	Random (340)	Adults	Japanese	Cw3 positively associated		23
Persistence (168)	Random (174)	Adults		A3, A11, B35, B51 positively associated	1) Controls unexposed 2) Serol typing 3) DQA, DQB not tested	24

Abbreviations: CI, class I; Serol, serological; CAH, chronic active hepatitis; HD, hemodialysis.

Lastly, a study of adults from Qatar detected different class II associations, but only 31 of the 131 controls were anti-HBs positive. Using serological class II typing, they showed DR7 to be a risk factor and DR2 to be protective. No difference in the frequency of DR6 (the supertype for the DRB1*1302 allele) or of DR4, which is in linkage disequilibrium with DQB1*0301, was observed.

Thus, one particular allele has not been clearly identified in association with HBV persistence. This ambiguity may be attributable to several possibilities including (1) a complex interaction involving multiple alleles, (2) differences among ethnic groups, (3) an association with a class I allele that has not been identified with molecular typing, or (4) an association with a gene in linkage disequilibrium with an HLA allele. Multicohort studies may be needed to clarify the data.

Theoretically, as first proposed by Zinkernagel and Doherty, heterozygosity at MHC loci could be advantageous for viral clearance since individuals who are fully heterozygous have twice as many alleles with which to present antigen than those who are fully homozygous.[40] For example, there are three classical class I loci (HLA-A, -B, -C), so an individual who is heterozygous at all loci has six different alleles with which to present antigen, but an individual who is fully homozygous has only three different alleles. Among HIV–infected individuals, those who are fully heterozygous for class I alleles are less likely to progress rapidly to AIDS.[41]

15273350, 2000, 4, Downloaded from https://onlinelibrary.wiley.com/doi/10.1053/he.2000.4316, Wiley Online Library on [15/10/2025]. Thursz and coworkers examined this in The Gambia and found significantly fewer individuals who were heterozygous for the class II alleles, DR and DQ, in the persistently infected compared with the transiently infected group.[42] This heterozygote advantage was also suggested in Thio and coworker's study but was not statistically significant.[14]

Three studies have examined the relationship between HLA and disease severity as determined by liver histology in persistently HBV–infected individuals.[22,30,39] None of these results have been reproduced.

The HLA association data thus far suggests that class II alleles may be more important in generating an effective immune response against HBV than class I alleles. The fact that antibodies to HBsAg are protective also implicates class II antigens as primary effectors against HBV infection. However, class I molecular typing has not been performed in a large study to date, so the role of class I awaits a more thorough investigation.

Other Candidate Genes. Tumor necrosis factor (TNF)-α, mannose binding protein (MBP), and the vitamin D receptor have been examined as potential candidate genes given that each of them may play a role in HBV pathogenesis. Patients chronically infected with HBV have increased levels of TNF-α and an upregulation of TNF-α receptors.[43,44] Also, in a HBV transgenic mouse model, CTL secretion of TNF-α is able to stop HBV gene expression.[45] Given these data, it is plausible that polymorphisms in the TNF-α gene may influence HBV persistence. This gene is located within the class III region of the MHC complex, and two polymorphisms in its promoter region, at positions -308 and -238, alter TNF-α expression.[46,47] The -238 promoter variant was significantly associated with HBV persistence in a cohort of 71 chronically and 32 transiently HBV–infected German patients.[48]

MBP affects inate immunity by activating the classical complement pathway and by acting as an opsonin binding directly to carbohydrate moieties on bacterial cell walls and to C1q receptors.[49,50] Several mutations in the MBP gene (codons 54, 57, and 52) and its promoter lead to low serum concentrations abolishing its ability to both activate complement and to act as an opsonin.[51] The HBV envlope contains a mannose-rich oligosaccharide to which MBP could potentially bind; thus these mutations have been investigated. One study compared a group with chronic HBV hepatitis (33 British Caucasians, 20 Asians, and 10 Others) to 98 British Caucasians and 123 Chinese controls with unknown exposure to HBV.[52] The codon 52 mutation of the MBP gene in British Caucasians, but not in the Asians, was associated with persistent HBV infection. Data from Chinese investigators supports this lack of assoiation between MBP polymorphisms and HBV persistence in Asians, but these investigators found the codon 54 mutation to be associated with symptomatic persistent infection.[53] In German Caucasians and in Gambians, these MBP polymorphisms were not asociated with chronic infection.[54,55]

In addition to its role in calcium regulation, the active form of vitamin D is an immunomodulatory hormone that inhibits the Th1 response and activates the Th2 response.[56] The vitamin D receptor gene has two known polymorphisms that have been found to be associated with tuberculosis, leprosy, and HIV.[57,58] Investigators in The Gambia have also studied these polymorphisms in relationship to HBV infection and found the tt genotype in one polymorphism to be associated with viral clearance.[57]

Discussion of HBV and Host Genetics. Thus far, the only reproducible association between host genetics and HBV infection involves HLA class II alleles, although the specific allele has varied between studies. If indeed specific alleles of the class II loci prove to be particularly efficient in viral clearance or slowing disease progression, then it follows that a CD4+ helper T cell response will be implicated as a critical factor in viral clearance. On the other hand, strong class I associations would suggest that a CD8+ CTL response is a critical factor in eliminating HBV. A primary role for class I involvement is a reasonable postulate because clearance of nonlytic viruses requires an efficient CTL response to eliminate the infected cells. A class I effect cannot be ruled out because few studies have addressed such a relationship and none have employed rigorous class I typing methodology using a large cohort. Further studies, including a multicohort study, are needed to clarify these preliminary associations and to investigate other potential candidate genes.

Hepatitis C Virus

Natural History. Hepatitis C virus is a bloodborne pathogen that is contracted in most cases via injection drug use and blood transfusions.[59] In contrast to adult-acquired HBV infection, the majority (75%-85%) of HCV infections persist. HCV antibody (anti-HCV) persists for years after HCV infection, even in those with self-limited infections. Thus, the presence of HCV RNA is used clinically to differentiate viral clearance from persistence. Because viremia can be intermittent in the first year of infection, demonstration of repeated presence or absence of HCV RNA is necessary to ascertain the outcome of an acute HCV infection.[60]

Genetic studies to date have examined 3 aspects of HCV infection: (1) clearance, (2) progression (cirrhosis), and (3) susceptibility to infection. The first, viral clearance, should be defined as a positive anti-HCV and two negative viral RNA tests at least six months apart; whereas, persistence of HCV implies continued HCV RNA positivity over a one-year period. In the second outcome, disease progression, the degree of liver damage can be semiquantitatively assessed by a system used to score liver biopsies, namely the histological activity index. Alternatively, clinical evidence of liver failure can be used. It is important to note that serious liver disease can be present without symptoms, potentially leading to misclassification of cases as controls. Thus, studies of HCV disease progression must include either large numbers of asymptomatic controls or those found to have limited disease on biopsy. Whether differential susceptibility to HCV infection actually occurs is not known because exposure is difficult to prove without an experimental model.

HLA Studies. Tables 2 through 4 outline statistically significant HLA associations from journal articles published between 1990 and 1998 for HCV outcomes of clearance, progression, and susceptibility to infection. These outcomes are discussed separately below.

Clearance. Three studies have examined class II associations with HCV clearance,[16-18] all of which defined clearance over a six-month period (Table 2). In these studies, DQB1*0301 was associated with clearance; Cramp et al. also identified DRB1*04 and DQA1*03 as protective alleles, which are in strong linkage disequilibrium with DQB1*0301. DRB1*1101, which is also in linkage disequilibrium with DQB1*0301, was associated with clearance in the Alric et al. study, and DRB1*11 was associated in the study by Minton

et al. The studies by Alric et al. and Cramp et al. suggest a role for DQB1*0301 in viral clearance and that two different DRB1 alleles were simply hitchhiking on DQB1*0301 in different populations. However, the study by Minton et al. suggests a stronger association for DRB1*11 than for DQB1*0301. None of these studies examined class I alleles.

Progression (Liver Failure). A number of additional studies have considered the association of HLA alleles with progression of liver disease[19-21,61,62] (Table 3). Two Japanese studies compared HCV carriers with normal liver function tests and normal histology with patients with elevated liver function tests and cirrhosis, respectively.[61,62] In both studies, DQB1*0401, DRB1*0405, and the two-locus haplotype consisting of these alleles were more frequent in those who developed chronic liver disease. However, because Kuzushita et al. also typed class I alleles, they showed that subjects with the three-locus haplotype, HLA-B54-DQB1*0401-DRB1*0405, were 13 times as likely to have liver injury relative to those with the two-locus haplotype without B54. In addition, a total of five class II alleles were suggested as protective against HCV disease progression between these two studies. Of the five, only DRB1*1302 showed the same trend for protection in these and two other Japanese studies.[19,21] DRB1*1101, which was associated with viral clearance,[17] was associated wih slower disease progression in two studies.[21,61] Additionally, Peano et al.[20] showed an inverse relationship between disease severity and frequency of DR5, which includes the allele DQB1*0301 associated with HCV clearance.[16,17]

Susceptibility to Infection. Several studies have attempted to examine susceptibility to HCV infection by comparing HLA alleles in individuals who are anti-HCV–positive with either the general population or with people who are anti-HCV–negative (Table 4).[25-29,31,63-65] Because the assumption cannot be made that the general population has been exposed to HCV, true associations may be missed by this experimental design. In addition, identification of individuals who have been exposed to HCV but remain seronegative is difficult.

One well-controlled study of the association of class II alleles with susceptibility to HCV infection compared 186 anti-HCV–positive patients, 121 of whom were HCV RNA–positive, to 328 anti-HCV–negative patients in a renal transplant clinic.[63] The primary mode of exposure was via multiple

blood transfusions, although the authors did not demonstrate an equivalent exposure rate in the two groups. Serological methods of HLA typing did not detect significant class I or class II differences between the groups. Congia et al. compared 116 anti-HCV–positive thalassemics to 30 anti-HCV–negative thalassemic controls and 606 ethnically similar controls.[64] The thalassemics had all been exposed to HCV through multiple blood transfusions. The haplotype DRB1*1601-DQB1*0502 was more frequent in the HCV–negative thalassemic controls relative to the anti-HCV–positive individuals. Several other studies have identified associations between class I and/or class II alleles and HCV infection,[25-29] but class I typing was performed using serological techniques, and controls always involved individuals who were unlikely to have been exposed to the virus. In general, among these studies, many different HLA associations were identified, but a few supported data from studies of HCV clearance and progression. Tibbs et al.[25] demonstrated that the allele DQA1*03, which was shown to favor clearance, was associated with protection against HCV infection. In a German study, DRB1*1302, which is associated with slower disease progression,[19,21] was shown to have decreased frequency in HCV–infected individuals compared with controls.[27] DR4 and DQB1*0401 were more frequent in Japanese HCV–infected subjects compared with random controls,[26] and in a Japanese study of progression, both of these alleles are associated with more rapid progression.[62]

A comparison of results in each of the three outcomes presents a wide array of HLA alleles that are associated with HCV infection. It is plausible that several HLA alleles may play a role in HCV infection or that these alleles are in linkage disequilibrium with another gene associated with HCV pathogenesis. Alternatively, these differences may be related to the small number of subjects and ethnic diversity of these studies and point to the need for a large, multi-ethnic confirmatory study.

Other Gene Markers. The two other candidate genes that have been studied in connection with HCV persistence are TNF-α and the hemochromatosis gene, HFE. Mutations in the TNF-α gene have been proposed as candidate genes since TNF-α levels are elevated in HCV infection perhaps because of production by CTLs in the liver.[66] In a study of 82 persistently HCV–infected patients and 99 controls, the -238A promoter variant was significantly associated with persistent HCV infection.[67]

HFE was recently discovered and is beginning to be studied in HCV infection because of the potential affect of iron on HCV pathogenesis. Iron may promote HCV replication, increase oxidative stress, deplete hepatoprotective factors, or impair host immunity. HFE is a MHC-class-I–like gene located on chromosome 6p telomeric to the HLA-A complex, which has two identified mutations. The first is at amino acid position 282 (C282Y) and the second is at amino acid position 63 (H63D). It is thought that the protein encoded by the HFE gene may directly limit the amount of iron absorbed in the small intestine or may regulate gene products that control iron absorption; therefore, these mutations may lead to increased iron absorption.[68]

A few studies have investigated the role of these mutations in individuals with chronic HCV infection. Hezode and coworkers found no difference in the frequency of heterozygosity for the C282Y mutation between HCV–infected patients with chronic active hepatitis and the general population.[69] Kazemi-Shirazi and coworkers compared both mutations between chronically HCV–infected patients and random controls.[70] There was no difference in the frequency of either mutation between the groups, however, iron overload was more common in patients with an HFE gene mutation. These results led them to conclude that the C282Y mutation contributes to but does not fully explain iron accumulation in chronically HCV–infected persons. Smith et al. studied 137 people with chronic HCV hepatitis and concluded that individuals heterozygous for the C282 mutation have more fibrosis but only minor increases in iron stores.[71] Overall, the data do not convincingly show a role between HFE mutations and HCV disease progression, although the studies to date have been small.

Discussion of Host Genetics and HCV. The literature on the host genome and HCV presents some reproducible HLA associations although further study is needed to convincingly identify alleles that affect response to infection and disease outcome. DQB1*0301 is associated with clearance[16,17] and with less severe disease,[20] but a more rigorous analysis of the other class II and class I alleles is essential to determine whether DQB1*0301 is simply hitchhiking with the actual protective allele at another HLA locus or another gene. As in HBV, class I associations have not been examined with rigorous class I typing methodology, and examination of candidate genes has just begun.

SUMMARY

The immunogenetics of chronic viral hepatitis is an immature field, but the molecular tools are becoming available that will allow a more thorough exploration of this area. Inconsistencies in the data presented may be related to inaccurate and/or low resolution HLA typing methods, linkage disequilibrium between genes, ethnic differences in the populations studied, and small sample sizes. In addition, comparison of HBV studies is complicated by differences in immune responses depending on age at acquisition of infection. Genetic associations found in some of these studies support the hypothesis that there is a genetic basis for viral hepatitis outcomes, but a multi-cohort study may be required to overcome the limitations of previous studies.

Finding an association between a gene and a viral hepatitis outcome does not imply causality, but instead it opens new avenues to explore and to understand the pathogenesis of these viruses. Thus, such genetic studies can only begin to answer questions about the factors that influence the outcome of an acute viral hepatitis infection. Further studies based on this information include finding a medical basis for the association and embarking on functional studies of the implicated genes. Such studies can provide clues to the pathogenesis of both HBV and HCV and may provide a rationale on which to base future therapeutic strategies.

Summary

Given the coronavirus disease 2019 (COVID-19) pandemic, investigations into host susceptibility to infectious diseases and downstream sequelae have never been more relevant. Pneumonia is a lung disease that can cause respiratory failure and hypoxia and is a common complication of infectious diseases, including COVID-19. Few genome-wide association studies (GWASs) of host susceptibility and severity of pneumonia have been conducted. We performed GWASs of pneumonia susceptibility and severity in the Vanderbilt University biobank (BioVU) with linked electronic health records (EHRs), including Illumina Expanded Multi-Ethnic Global Array (MEGA^{EX})-genotyped European ancestry (EA, n= 69,819) and African ancestry (AA, n = 15,603) individuals. Two regions of large effect were identified: the *CFTR* locus in EA (rs113827944; OR = 1.84, p value = 1.2×10^{-36}) and *HBB* in AA (rs334 [p.Glu7Val]; OR = 1.63, p value = 3.5×10^{-13}). Mutations in these genes cause cystic fibrosis (CF) and sickle cell disease (SCD), respectively. After removing individuals diagnosed with CF and SCD, we assessed heterozygosity effects at our lead variants. Further GWASs after removing individuals with CF uncovered an additional association in *R3HCC1L* (rs10786398; OR = 1.22, p value = 3.5×10^{-8}), which was replicated in two independent datasets: UK Biobank (n = 459,741) and 7,985 non-overlapping BioVU subjects, who are genotyped on arrays other than MEGA^{EX}. This variant was also validated in GWASs of COVID-19 hospitalization and lung function. Our results highlight the importance of the host genome in infectious disease susceptibility and severity and offer crucial insight into genetic effects that could potentially influence severity of COVID-19 sequelae.

The COVID-19 pandemic is a serious threat to public health; over 58 million confirmed cases from 191 countries have been reported (see "Coronavirus Disease 2019" and "COVID-19 Map" in Web resources). Pneumonia is a common complication of COVID-19 and may lead to acute respiratory distress syndrome (ARDS) and death.[1] In the context of the COVID-19 pandemic, identifying factors that influence host susceptibility to and severity of pneumonia has never been more important. Several clinical factors and underlying conditions that influence susceptibility to and severity of community-acquired pneumonia in adults have been identified, including age, chronic bronchitis or chronic obstructive pulmonary disease (COPD), asthma, obesity, diabetes, and others.[2] These risk factors have also been observed in COVID-19-associated pneumonia.[3–6] However, little is known about the role of the host genome in the susceptibility to and severity of pneumonia.

There is a paucity of studies interrogating host genetic susceptibility to and severity of pneumonia. While previous studies identified suggestive associations with childhood pneumonia, survival from sepsis due to pneumonia, and severe pneumonia following influenza A/H1N1 infection,[7–9] three genome-wide significant associations with pneumonia, one in the *HLA* class I region, have been mapped,[10] and two additional genome-wide significant independent hits on chromosome 15 were identified in a meta-analysis of the UK Biobank and FinnGen.[11] To identify additional genetic loci impacting pneumonia in existing data resources, we aimed to identify genetic variants associated with susceptibility to and severity of pneumonia by leveraging electronic health records (EHRs) from a large-scale biobank.

The Vanderbilt University Medical Center biobank (BioVU) comprises over 110,000 participants with linked EHRs genotyped on the Illumina Expanded Multi-Ethnic Genotyping Array (MEGA^{EX}) or another genome-wide array. We defined pneumonia cases by using 81 pneumonia-related diagnosis codes (Supplemental box) from the International Classification of Diseases Ninth Revision, Clinical Modification (ICD-9 CM) and used the subjects without any diagnosis of pneumonia as population-based controls. We used hospitalization status as a proxy for severity, determined via relevant Current Procedural Terminology codes recorded within 5 days of pneumonia diagnosis (Supplemental box). In 69,819 MEGA^{EX}-genotyped European ancestry (EA) individuals, 8,889 individuals with pneumonia were identified, including 5,774 with pneumonia-associated hospitalization (inpatients). In 15,603 MEGA^{EX}-genotyped African ancestry (AA) individuals, we

[a] In UK Biobank, only the comparison between individuals with pneumonia versus the general population is available.

[b] In COVID-19 HGI, we used "C2" phenotypes, which compared individuals with COVID-19 to population controls, as susceptibility and "B1" results, which compared hospitalized individuals with COVID-19 to non-hospitalized control individuals with COVID-19, as severity.

identified 1,710 individuals with pneumonia, of which 1,043 were inpatients. In both EA and AA subjects, we observed a significantly higher prevalence of obesity, COPD, diabetes, asthma, and liver and renal diseases in subjects with a pneumonia diagnosis (Tables S1 and S2). We sought replication of our top findings in two independent datasets: UK Biobank ($n = 451{,}305$) and 7,985 non-overlapping BioVU subjects, who were genotyped on arrays other than MEGA^{EX} (non-MEGA^{EX}) (Tables S3–S5).

Genetic imputation in MEGA^{EX}-genotyped subjects was conducted with minimac4 on the Michigan Imputation Server[12] with a reference panel of Haplotype Reference Consortium r1.1. A total of 39,635,008 SNPs was imputed. In EA, only 7,167,360 SNPs with an imputation info score greater than 0.4 and minor allele frequency (MAF) greater than 1% were used for further GWAS and GReX imputation. In AA, 13,633,982 SNPs passed quality control filter. A more stringent MAF cutoff was applied in the comparison of AA pneumonia inpatient versus outpatient because of the smaller sample size ($n = 1{,}710$; 7,594,451 variants with MAF $> 5\%$ and imputation info score > 0.4). Because of the existence of genetic relatedness in BioVU, we utilized a generalized estimating equations (GEE) model to perform GWASs with SUGEN.[13] Since SUGEN requires known family networks representing close relatedness within a dataset, we used PRIMUS to reconstruct non-directional family networks, including all first- and second-degree,[14] and we used ERSA to verify the families with more than five members.[15] Among MEGA^{EX}-genotyped subjects, 5,019 families (size 2 or greater) were identified in BioVU EAs and 1,699 families in BioVU AAs. We included age, sex, and three principal components to capture genetic ancestry as covariates in the association tests.

Separate GWASs for susceptibility and severity of pneumonia were performed in EA and AA, each of which identified a major locus. In EA, rs113827944 (MAF $=$ 2.1%) was significantly associated with both pneumonia susceptibility and severity (affected individuals versus control individuals, odds ratio [OR] $= 1.84$, p value $= 1.2 \times 10^{-36}$; inpatients versus outpatients, OR $= 1.70$, p value $= 4.0 \times 10^{-9}$). Replication of this lead SNP was observed in BioVU non-MEGA^{EX}-genotyped EA (affected individuals versus control individuals, OR $= 1.92$, p value $= 2.4 \times 10^{-6}$). Another SNP, rs334 (p.Glu7Val, MAF $=$ 5.8%) was significantly associated with both susceptibility and severity in AA (affected individuals versus control individuals, OR $= 1.63$, p value $= 3.5 \times 10^{-13}$; inpatients versus outpatients, OR $= 2.56$, p value $= 4.5 \times 10^{-12}$) (Table 1, Figures 1 and 2, and Figures S1–S3).

The lead SNP in EA, rs11382794, is located in the intron of cystic fibrosis transmembrane conductance regulator (*CFTR* [MIM: 602421]), the causal gene for cystic fibrosis (CF [MIM: 219700]). CF causes abnormally thick mucus that blocks airways, leading to chronic infections, persistent inflammation, airway remodeling, and progressive respiratory failure.[16,17] Both acute and chronic lung infections are major contributors to morbidity and mortality in individuals with CF.[18,19] In a study of 19,802 CF carriers (individuals with one defective copy of *CFTR*) and 99,010 control individuals, CF carriers were more likely than non-carriers to have pneumonia (OR $= 1.16$), a personal history of recurrent pneumonia (OR $= 2.76$), and other respiratory infections.[20]

The top finding in AA, rs334, is a nonsynonymous variant in hemoglobin subunit beta (*HBB* [MIM:141900]) and the causal mutation for SCD, including sickle cell

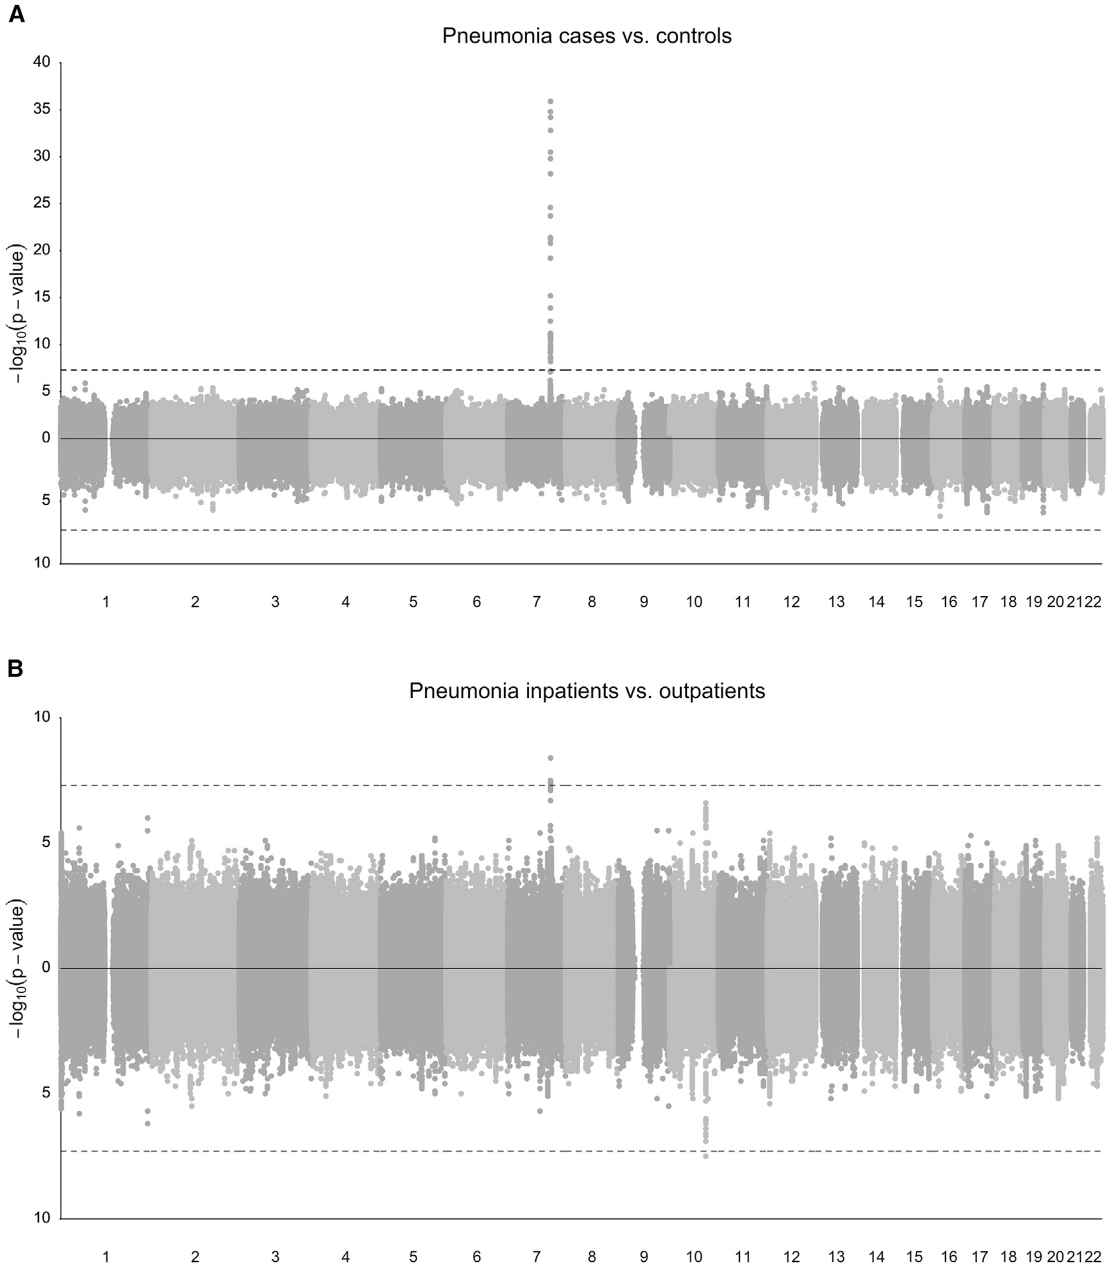

Figure 1. SNP associations with pneumonia in BioVU MEGA^{EX}-genotyped EA
(A) Miami plot of pneumonia susceptibility (individual with pneumonia versus control individuals) with (top) and without (bottom) individuals diagnosed with CF.
(B) Miami plot of pneumonia severity (pneumonia inpatients versus outpatients) with (top) and without (bottom) individuals diagnosed with CF.

anemia (SCA [MIM: 603903]). The relationship between SCA and pneumonia risk has been previously described in epidemiological studies.[21] Children with SCA are more likely to have pneumonia and influenza (OR = 7.38) and acute respiratory infections (OR = 1.29).[22] Acute chest syndrome (ACS) is a common complication of SCD and can be triggered by pneumonia and vaso-occlusive crises and is the leading cause of death in individuals with SCA.[23] Clinically differentiating between ACS and pneumonia can be difficult, and they often overlap in the EHR.

Our two initial findings provide genetic support of previously observed epidemiological predictors of severe pneumonia risk, namely, the two autosomal recessive disorders CF and SCD. Previous studies have also reported associations between carrier status for *CFTR* and CF-associated symptoms.[20] In contrast, SCA carriers had slightly lower risk of pneumonia and influenza (OR = 0.93) compared to subjects with normal hemoglobin,[22] although pneumonia severity was not studied. We applied Fisher's exact test to investigate the effect of the risk allele in

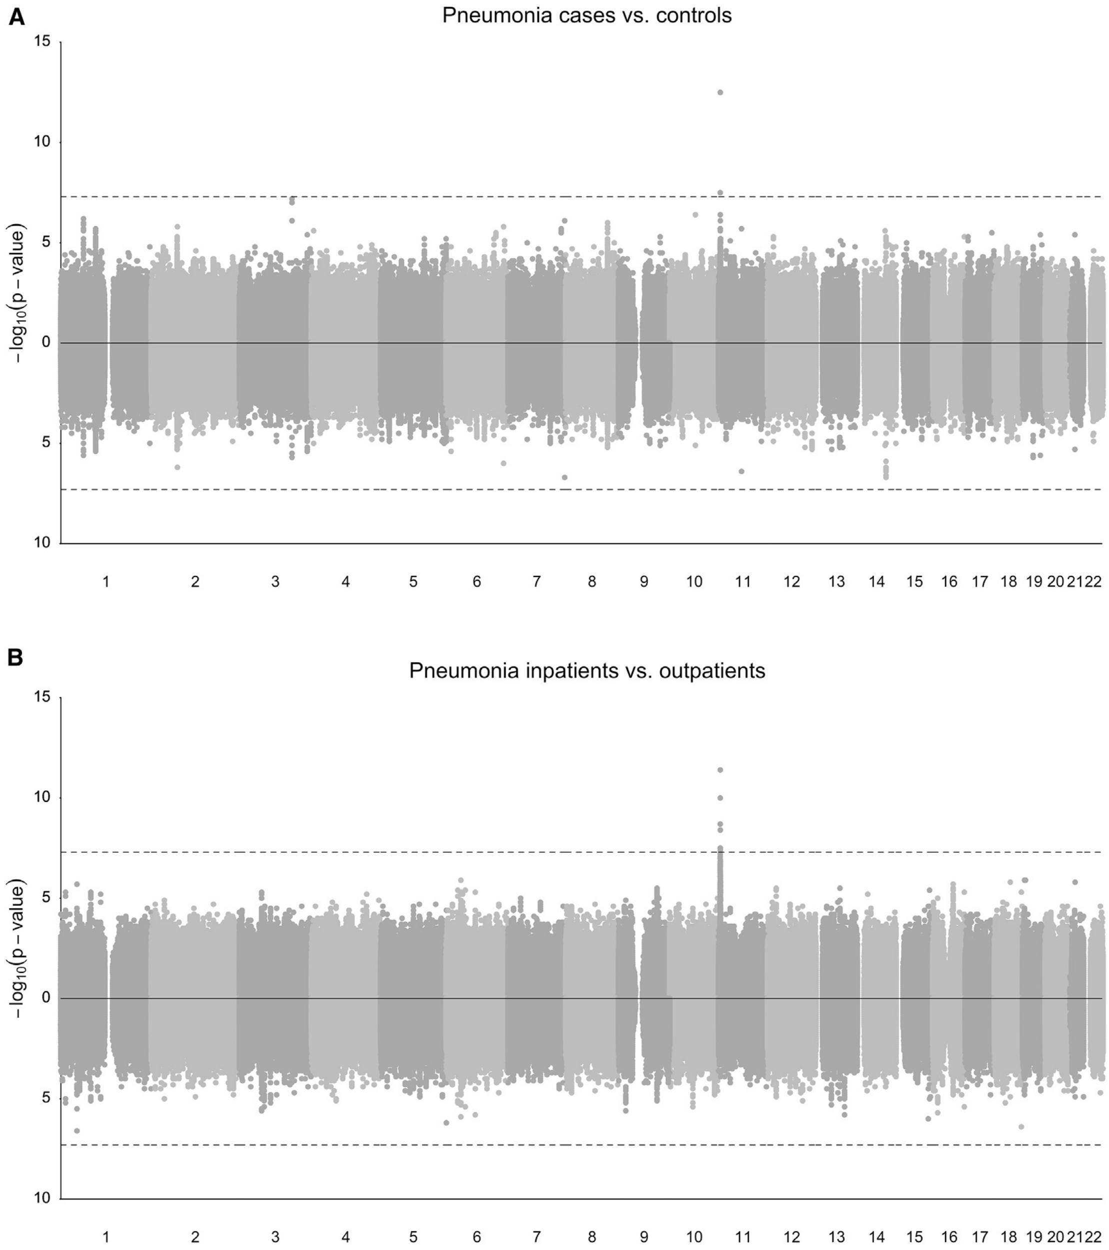

Figure 2. SNP associations with pneumonia in BioVU MEGA^{EX}-genotyped AA
(A) Miami plot of pneumonia susceptibility (individual with pneumonia versus control individuals) with (top) and without (bottom) individuals diagnosed with CF and SCD.
(B) Miami plot of pneumonia severity (pneumonia inpatients versus outpatients) with (top) and without (bottom) individuals diagnosed with CF and SCD.

heterozygous carriers of the risk allele compared to those homozygous for the reference allele. We found heterozygous carriers of rs113827944 (*CFTR*) were at greater risk of developing pneumonia (OR = 1.38, p value = 1.9×10^{-7}), including in sensitivity analyses excluding all individuals with diagnosed CF (OR = 1.17, p value = 0.019; Table 2). Heterozygous carriers of rs334 (*HBB*) were at greater risk of pneumonia-associated hospitalization (OR = 1.55, p value = 0.023), and sensitivity analyses excluding 138 individuals diagnosed with CF and SCD slightly attenuated this effect (OR = 1.49, p value = 0.109), most likely because of a reduction in power. Heterozygote effects observed herein are consistent with an intermediate phenotype or an undetected second variant contributing to compound heterozygosity.[20,24,25]

To identify additional effects masked by the strong effects of *CFTR* and *HBB*, we repeated GWASs after removing individuals diagnosed with CF and SCD. In EA, after removal of individuals with CF, we identified a genome-wide significant signal in *R3HCC1L* (rs10786398, MAF = 30.7%, OR = 1.22, p value = 3.5×10^{-8}, Table 1, and Figures 1 and 3). Replication of effects at this gene were

observed in a distinct haplotype in BioVU AA (rs7086391, MAF = 16.9%, OR = 1.42, p value = 1.14×10^{-3}, multiple-testing-corrected p value = 0.0490, Figure S4) and at a distinct sentinel variant in UK Biobank EA (rs884811, MAF = 44.2%, OR = 1.05, p value = 3.49×10^{-3}, multiple-testing-corrected p value = 0.0198, Table 1). We note that this region of the genome exhibits low linkage disequilibrium: the lead variants from our discovery analyses and from the UK Biobank validation had an R^2 of 0.55 in the BioVU data despite their being less than 3 kb apart (Figure S5). We also observed effects of rs10786398 in the latest release of the COVID-19 Host Genetics Initiative GWAS comparing hospitalized individuals with COVID-19 to non-hospitalized affected individuals (OR = 1.19, MAF = 31.4%, p value = 0.037),[26] indicating relevance of this variant for susceptibility to and severity of COVID-19. A previously published meta-analysis of lung function in UK Biobank and the SpiroMeta consortium provided additional validation of lead variants in *R3HCC1L* (Table S6).[27] *R3HCC1L* encodes a coiled-coil domain-containing protein. Variants in its promoter region have been reported to be associated with inflammatory skin disease[28] and body mass index.[29,30] However, the molecular function of *R3HCC1L* is still unclear and more studies are needed to clarify its role in the pathogenesis of pneumonia.

In AA, after removal of individuals with CF and SCD, an additional SNP near *UQCRFS1* (MIM: 191327) and non-coding RNA LOC105372352 (rs148218440, MAF = 2.4%; OR = 2.21, p value = 3.6×10^{-8}; Figures S6 and S7) was identified in the comparison of AA pneumonia inpatients and age-, sex-, and ancestry-matched control individuals. *UQCRFS1* encodes a Rieske iron-sulfur protein, which is part of the mitochondrial respiratory chain.[31] Rare mutations in *UQCRFS1* have been previously reported as the cause of a mitochondrial disorder (MIM: 618775).[32] Further, *Uqcrfs1* deletion in mice abolishes mitochondrial reactive oxygen species that are required for antigen specific T cell responses, a hallmark of the adaptive immune response.[33] We did not observe replication of rs148218440 in BioVU non-MEGA^{EX} AA (Table 1), however we note that this analysis was underpowered to detect effect (n = 292 affected individuals and 1,145 control individuals, Table S4); UK Biobank did not have enough

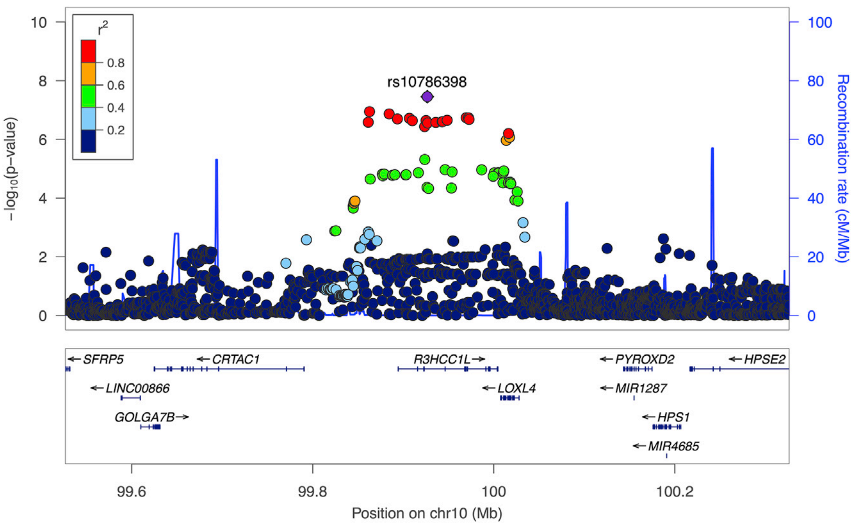

Figure 3. LocusZoom plot of *R3HCC1L* with the genome-wide association study results of pneumonia inpatients versus outpatients from BioVU MEGA^{EX}-genotyped EA excluding CF-affected individuals
Linkage disequilibrium and recombination rate estimates come from 1000 Genomes Project phase 3 European superpopulation reference data.

AA individuals with pneumonia to perform a replication analysis ($n = 76$ affected individuals and 9,272 control individuals, Table S5).

To further investigate the functional role of associated variation at our lead genes, we utilized PrediXcan to impute the genetically regulated expression (GReX) in MEGA^{EX}-genotyped EA and AA with the tissue-specific models trained by GTEx V8.[34,35] The association tests were conducted with SUGEN and adjusted for three principal components, sex, and age (Table S7 and Figures S8 and S9). The GReX of *R3HCC1L* in lungs is significantly associated with severity of pneumonia in EA ($\beta = 1.140$, p value $= 2.0 \times 10^{-7}$). In addition, the association of the GReX of *HBB* with pneumonia susceptibility in EA offers additional evidence of its role ($\beta = 30.670$, p value $= 7.3 \times 10^{-4}$). GReX of *CFTR* is not well captured in lung tissue,[34] however GReX of this gene in other tissues are significantly associated with pneumonia susceptibility in EA (heart left ventricle, $\beta = 0.464$, p value $= 3.7 \times 10^{10}$).

Moreover, we estimated the heritability of pneumonia susceptibility and severity in MEGA^{EX}-genotyped EA. We used genome-wide complex trait analysis (GCTA)[36] to construct a genetic relatedness matrix and calculated the proportion of phenotypic variance explained by the matrix. The SNP-based heritability (h^2) for susceptibility to pneumonia is estimated to be 0.029 and 0.026 after removing individuals diagnosed with CF (Table S8). As expected due to greater similarity of exposure in affected individuals and control individuals, genetic variation explains a larger portion of pneumonia severity compared to susceptibility ($h^2 = 0.121$; after removing individuals with CF, $h^2 = 0.150$). Our results are similar to previous estimates in UK Biobank (0.075 for self-reported pneumonia, 0.15 for pneumonia inpatient).[37]

The data used for the present discoveries exhibit several key limitations. Extracting accurate phenotypes from EHR data is a well-known challenge[38] and most likely results in some misclassification of cases. Such misclassification most likely reduces power to detect effects but is unlikely to introduce systemic bias that would invalidate results. Additionally, distinguishing viral and bacterial pneumonia via clinical criteria is challenging, and data on positive cultures of blood or pleural fluid for bacterial or positive nasopharyngeal sample or positive serology for viral were not widely available in BioVU. Despite these challenges, we were able to detect four loci linked to pneumonia, including two regions. Further research will be required to differentiate the genetic architecture of specific pneumonia etiologies and to confirm the *UQCRFS1* association, and functional studies will be needed to determine the biological mechanism underlying both signals.

In summary, we leveraged a large-scale biobank to identify genetic variants associated with the susceptibility and severity of pneumonia. Two clinically relevant Mendelian disease genes, *CFTR* and *HBB*, were implicated. These important genetic results indicate that individuals with CF and SCA are at heightened risk for development of and severe outcomes from pneumonia, an effect which may translate to COVID-19 outcomes. Heterozygous carriers of the CF risk allele demonstrated elevated risk of pneumonia susceptibility, and carriers of the SCD risk allele demonstrated elevated risk for pneumonia severity. These findings may have important implications for genetically informed patient care in infectious lung disease. They are also critically important in the context of the COVID-19 pandemic, and future studies will be needed to establish whether these carriers exhibit a silent, heightened risk for poor outcomes from COVID-19 as well. We also identified two additional pneumonia-related genes: *R3HCC1L* and *UQCRFS1*. Although we were most likely underpowered to replicate effects of *UQCRFS1* variation in AA in our data resources, we successfully replicated *R3HCC1L* effects in two independent datasets and validated effects of *R3HCC1L* in independent GWASs of COVID-19[26] and lung function.[27] Characterizing host genome effects on infectious disease susceptibility and severity can offer important insight into the molecular etiology of risk; our findings may help elucidate pathophysiological processes for pneumonia, an important COVID-19 sequelae.

Data and code availability

The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Supplemental Data

Supplemental Data can be found online at https://doi.org/10.1016/j.ajhg.2020.12.010.

Acknowledgments

The authors would like to thank Austin McPhilamy for his help identifying ICD codes relevant to pneumonia phenotyping. Abstract: This review of human amoebiasis is based on the most current knowledge of pathogenesis, diagnosis, treatment, and Entamoeba/microbiota interactions. The most relevant findings during this last decade about the *Entamoeba* parasite and the disease are related to the possibility of culturing trophozoites of different isolates from infected individuals that allowed the characterization of the multiple pathogenic mechanisms of the parasite and the understanding of the host–parasite relationship in the human. Second, the considerable advances in molecular biology and genetics help us to analyze the genome of *Entamoeba*, their genetic diversity, and the association of specific genotypes with the different amoebic forms of human amoebiasis. Based on this knowledge, culture and/or molecular diagnostic strategies are now available to determine the *Entamoeba* species and genotype responsible for invasive intestinal or extraintestinal amoebiasis cases. Likewise, the extensive knowledge of the immune response in amoebiasis with the appearance of new technologies made it possible to design diagnostic tools now available worldwide. Finally, the understanding of the interaction between the *Entamoeba* species and the intestinal microbiota aids the understanding of the ecology of this parasite in the human environment. These relevant findings will be discussed in this review.

Keywords: amoebiasis; advanced diagnosis and treatment; pathogenesis; intestinal microbiota interaction

1. Introduction

The genus *Entamoeba* consists of at least seven different species (*E. histolytica*, *E. coli*, *E. hartmanni*, *E. polecki*, *E. dispar*, *E. moshkovskii*, and *E. bangladeshi*) that can inhabit the human intestine and one (*E. gingivalis*) that can be found in the human oral cavity [1]. Until today, the only species recognized as an etiologic agent of the amoebic invasive disease is *Entamoeba histolytica*, with the large intestine as the main target organ [2].

Amoebiasis is defined as the gastrointestinal infection caused by *E. histolytica* with or without clinical manifestations [2], and is responsible for the worldwide morbidity and mortality rates due to amoebiasis in children and young adults. The global significance of amoebiasis is widespread, with the highest burden of amoebiasis borne by those residing in developing countries, particularly the tropics and subtropics, where there are inadequate hygiene levels and access to sanitation [3]. The efforts being made in the study of amoebiasis epidemiology in developing countries allow us to have a deeper understanding of its global panorama [4,5]. The estimations of the worldwide burden of amoebiasis by the World Health Organization (WHO) indicated that approximately 500 million people were infected with the parasite and 10% of these individuals had invasive amoebiasis [6]. Some reports mention that more than 55,000 people die each year due to acute intestinal amoebiasis [7,8].

Amoebiasis is caused by the ingestion of food or water contaminated with cysts, the infective form of *E. histolytica*. Following excystation, the emerging trophozoites migrate to the large intestine [9]. The trophozoites (mainly for *E. histolytica*) can become virulent and invasive, where they start to destroy the mucous–epithelial barrier, thus inducing the overproduction of mucus, killing host cells, and provoking inflammation, subsequently causing amoebic colitis [10]. *Entamoeba histolytica* can be transmitted by asymptomatic hosts infected with cysts and patients with intestinal amoebiasis, who are the natural transmitters [11]. The *Entamoeba* cysts are resistant to desiccation in soil and can survive in humid environments and food or water for several weeks, and susceptible hosts exposed to the infection sources ingest the cysts, which then undergo excystation during their pass through the gastrointestinal tract [11,12]. When in excystation, each cyst produces eight vegetative forms or trophozoites, which are the motile form of the parasite [11]. Trophozoites multiply by binary fission and some of them may encyst and be excreted with stools [13]. In asymptomatic infections, *Entamoeba* species trophozoites live as commensal feeding on colonic microbiota and nutrients of the host and forming cysts that pass through stools to perpetuate a new life cycle by fecal–oral spreading (Figure 1) [4]. It should be noted that more than 90% of infections have an asymptomatic course and are often self-limited over different periods [14].

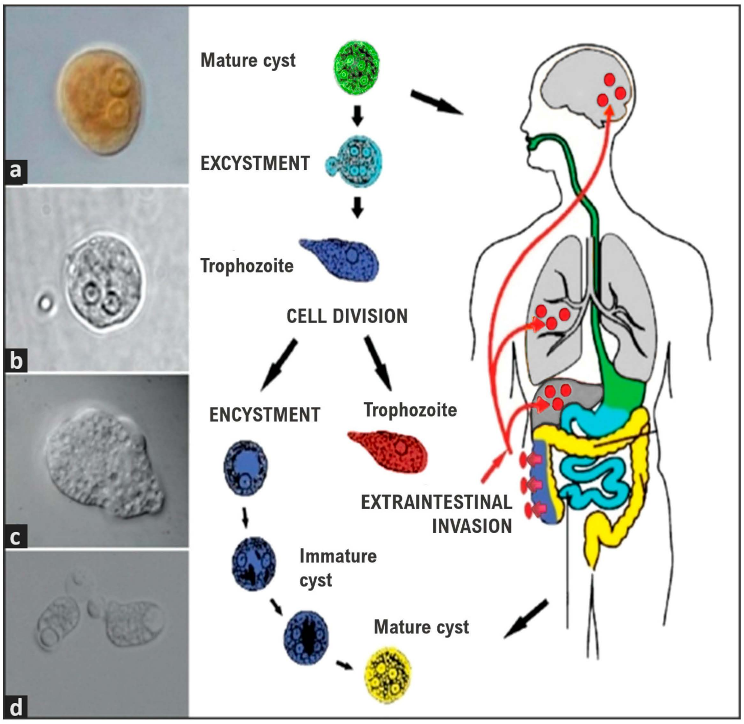

Figure 1. The life cycle of *E. histolytica*/*E. dispar.* Mature cysts (green) are swallowed along with food and water. The cysts pass through the stomach, but if the stomach is alkaline or when the cyst reaches the small intestine the cyst wall is damaged by trypsin, excystation starts (light blue). Trophozoites emerge (blue) and colonize the caecum and colon. Trophozoites are the infective amoeboid form which multiply by binary fission and can migrate to other tissues causing an extraintestinal invasion (red) or initiate encystment forming immature cysts and, finally, a mature cyst (yellow) to start a new cycle. (**a**) Mature cyst stained with 4% Lugol's solution (100× magnification); (**b**) Mature cyst without staining (100×); (**c**) Trophozoite observed with differential interference contrast (DIC) (100×); (**d**) Trophozoites of *E. histolytica* with phagocyted erythrocytes (DIC) (40×) in Ximénez et al. [11].

Amoebiasis is endemic in the developing countries of Central and South America, Africa, and Asia [3,15]. However, until now, the exact burden of amoebiasis in these countries has been difficult to determine, and reports can be affected by geographic region, study design, sample size, incubation, symptom severity, and the sensitivity of the diagnostic modality used. In addition, diagnostic capacities and surveillance are often limited in areas where *E. histolytica* is endemic [4,16].

2. Clinical Features

Following the 1997 documents by the World Health Organization, amoebiasis is defined as the infection of the protozoan parasite *E. histolytica* with or without clinical manifestations [2]. The spectrum of the disease ranges from asymptomatic infection to the development of a severe infection with amoebic colitis and/or amoebic liver abscesses [17]. Chronic non-dysenteric colitis is the most frequent form of amoebiasis in people of all ages, characterized by non-specific symptoms [3]. After exposure to the parasite, 80% of patients display symptoms over a few days to 4–6 weeks [11]. The natural history of invasive intestinal amoebiasis is an acute event, characterized by the presence of diarrhea that occurs days or weeks after exposure and does not last more than four to five weeks, although there are reports of its occurrence years later after exposure to a source of infection [11]. In the latter case, it is assumed that the cause–effect relationship is extremely difficult to corroborate [18]. The natural history of this clinical form can also mimic irritable bowel syndrome. Symptoms more relevant in this instance are periods of abdominal pain (colic) and auto-limited episodes of diarrhea alternating with constipation. However, both non-dysenteric amoebic colitis and irritable bowel syndrome are controversial themes in clinical practice [11]. A few individuals with *E. histolytica* infections develop extraintestinal features including liver abscesses, purulent pericarditis, lung abscesses, pneumonia, peritonitis skin lesions, and even cerebral abscesses, due to the dissemination of trophozoites via the blood circulatory system [19–21]. Of these clinical features, the liver abscess is the most common manifestation, and delay in diagnosis and treatment may cause fatalities.

2.1. Amoebic Liver Abscess

Amoebic liver abscess is a disease that can affect individuals of all ages; in some endemic areas, the incidence rates are higher in both children under 5 years and young adults. Males are also more prone to developing amoebic hepatic abscesses than females [3,11]. The most common symptoms suggestive of amoebic liver abscess are fever (38 °C), chills and diaphoresis, anorexia, and abdominal pain in the right upper quadrant that increases during inspiration. Pain also frequently radiates to the shoulder and back. Nausea has also been referenced but diarrhea is only occasionally mentioned (50% of cases) [11,22].

Hepatomegaly can be detected during digital percussion of the hepatic area and is always related to the dimensions of the abscess; patients can also display peritoneal signs (abdominal guarding or rebound). The absence of intestinal noises, jaundice, and pleural or pericardial rub are symptoms that should elicit alarm related to the rupture or imminence of rupture of the hepatic abscess [23].

2.2. The Severe Forms of Amoebiasis

The severe forms of amoebiasis are colon ameboma, fulminant necrotizing colitis, and toxic megacolon [24]. The appearance of symptoms, such as severe dysentery and pain with signs of peritoneal irritation (rebound), intense tenesmus, a fever (>38 °C), tachycardia, hypertension, nausea, and anorexia, are suggestive of the previously mentioned severe forms of intestinal amoebiasis [20]. The mortality rates of dysenteric syndrome due to *E. histolytica* are less than 1%, but mortality due to complications increases up to 75% [3]. Fulminant amoebic colitis is a rare complication of amoebiasis associated with high mortality, and can occur in more than 50% of cases with severe colitis [20,24]. The severe forms of invasive amoebiasis can be observed in young children, pregnant women, the elderly, and those with chronic diseases and individuals being treated with immunosuppressants or those with immunodeficiency disorders [11].

The circumstances that define the extraintestinal invasive behavior of some *E. histolytica* strains remain unknown today. However, this seems to be an infrequent event as suggested by the low morbidity rates of amoebic liver abscess and other extraintestinal forms of invasive amoebiasis compared with the prevalence rates of asymptomatic infections and intestinal disease, and fortunately, in the last decade, such complications are uncommon [25,26].

3. Diagnosis

Amoebiasis is an acute disease in which the most frequent symptoms are abdominal pain (colic) and the presence of diarrhea with mucus and/or blood, or a clear dysenteric syndrome, but fever and other systemic symptoms are infrequent [27]. In endemic areas, patients with clinical signs and symptoms including gastrointestinal upset and watery or bloody diarrhea should be suspected of intestinal amoebiasis and should be treated [28].

3.1. Macroscopy and Microscopy Analyses

The gold standard for the diagnosis of amoebiasis is the identification of the parasite, mainly in the feces of people infected with *Entamoeba*, where cysts and, rarely, trophozoites are identified. This identification is carried out by direct microscopy examination; the Faust–Ferreira concentration method has been the most widely used for microscopic identification [29]. While technically simple in approach, these techniques require the expertise of highly qualified technicians in the morphological identification of ova, cysts, and trophozoites to be feasible, and the sensitivity and specificity are no more than 80% [30]. This technique cannot differentiate between *E. histolytica* or *E. dispar*, but in some endemic communities, this is the only diagnostic technology available [31]. Where endoscopy examination is available, a colonoscopy can be of great help in the clinical diagnosis of invasive intestinal amoebiasis [20]. This procedure allows for the microscopic examination of samples taken directly from the characteristic flask-shaped ulcer produced by *E. histolytica* and from other sites of mucosal lesions.

On the other hand, a colonoscopy detects the presence of lesions related to the mentioned severe forms of intestinal amoebiasis and allows for the differential diagnosis of other pathologies, such as inflammatory bowel disease or colon carcinoma (Figure 2) [11].

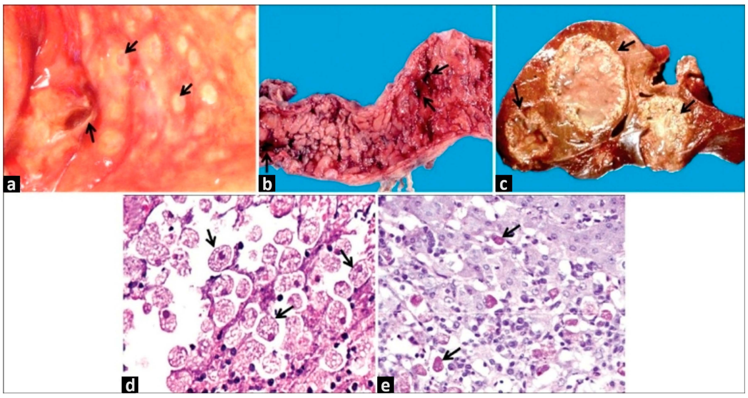

Figure 2. (**a**) Intestinal flask-shaped ulcers observed through rectosigmoidoscopy examination. Arrows indicate colonic ulcers. (**b**) Large bowel necropsy specimen from a case of fulminant amoebic colitis. Arrows indicate hemorrhagic ulcers and important intestinal mucosa necrosis. (**c**) Necropsy specimen of liver abscesses. Arrows indicate the three large abscesses. (**d**) Intestinal biopsy obtained from the edge of a flask-shaped ulcer where large numbers of trophozoites (HE and PAS stained, 60×) are visible. (**e**) Biopsy obtained from the edge of an amoebic liver abscess (HE and PAS stained, 20×). Notice the presence of trophozoites, hepatocytes, and many inflammatory cells. Courtesy Doctor Ruy Pérez-Tamayo in Ximénez et al. [11].

3.2. Imagen Diagnosis

In amoebic liver abscesses, in general, the right hepatic lobule is the most frequently affected due to the portal circulatory system of the right colon; however, the left lobule can be also affected [20]. Laboratory findings suggestive of amoebic liver abscess are the presence of leukocytosis, neutrophilia, increased globular sedimentation velocity, and high levels of alkaline phosphatase [3,32].

Thoracic X-ray data useful in the diagnosis of amoebic abscesses, as well as other types of hepatic abscesses, include the elevation of the right hemidiaphragm, atelectasis, or pleural effusion [3,33]. An ultrasound is the gold standard technique for the diagnosis of amoebic liver abscesses and is of tremendous importance in countries with limited medical and economic resources [34]. Several authors have mentioned the presence of a large single abscess as a frequent characteristic of amoebic liver abscesses; however, this characteristic is not a determinant of amoebic abscesses, and the pyogenic abscesses are also not characteristic of multiple abscesses [35,36].

Early lesions due to the amoebic invasion of hepatic parenchyma are multifocal (micro-abscesses) because of tissue destruction and necrosis by proteases from *E. histolytica*, and neutrophil recruitment to the site of infection [37]. The advantage of computed tomography (CT) scans and magnetic resonance is the detection of small abscesses and the high definition of the images. Moreover, other techniques not always available in endemic countries (e.g., gallium scans) can help differentiate between amoebic (cold images) and pyogenic abscesses (hot images). Thus, the difference is based on the absence (amoebic) or presence (pyogenic) of white blood cells in the abscesses [36,38].

3.3. Immunological and Molecular Diagnosis

During the last 10 years, diagnostics in amoebiasis have changed dramatically, considerably improving sensitivity and specificity. Some of the current techniques are based on immunological strategies, such as ELISA and different modalities of polymerase chain reaction (PCR). There are clear advantages in the bedside diagnosis and clinical laboratories of health institutions [31].

In our experience, immunologically based diagnostics tests for the detection of anti-amoebic antibodies in serum are excellent tests in hospitals, particularly in patients with liver abscesses, and their results are reproducible and reliable to perform the differential diagnosis between amoebic and pyogenic liver abscesses and determine the appropriate treatment [39,40]. The presence of the parasite can also be identified in the drainage of liver abscesses, even though trophozoites are not detected in these types of samples, it is possible to obtain the DNA of the parasite through molecular techniques. Likewise, in tissue biopsies of cutaneous or intestinal amoebiasis lesions, microscopic identification of the trophozoites and/or by PCR is possible. Advances in molecular diagnostics have improved our understanding and led to the recognition and separation of *E. histolytica* from nonpathogenic species of *Entamoeba*. Therefore, PCR has become a very sensitive and specific diagnostic method [31,40].

ELISA tests have been used both for the detection of antiamoebic antibodies in serum and for the capture of amoebic antigens in feces. However, the difficulty of differentiating a past infection from an active one considerably limited its use to identify patients requiring treatment; instead, it has been used for seroepidemiological studies [41–43], so there are many commercial tests that can even differentiate *E. histolytica* from *E. dispar*. These diagnostic kits allow for the generation of reliable results quickly by following simple instructions, but they are expensive due to the use of monoclonal Abs (mAbs) for antigen capture and are not routinely used in clinical laboratories.

Of these kits, the most popular mAbs for use against Gal/Lectin GalNAc are: the *E. histolytica* TechLab kit and the CELISA PATH kit (Cellabs, Brookvale, Australia), which were developed specifically to detect *E. histolytica* in stool samples, and the TechLab *E. histolytica* II (Blacksburg, VA, USA), which allows the detection of different epitopes between the Gal-lectins of *E. histolytica* and *E. dispar* [44–46]. The sensitivity and specificity of the

TechLab kits I and II vary by 80–99% and 86–98%, respectively [44]. Other kits include the Optimum S kit (Merlin Diagnostika, Bornheim-Hersel, Germany), which detects the components of the family of serine-rich proteins, the Alexon ProSpecT ELISA (Remel Inc., Lenexa, KS, USA), which detects an "AND *E. histolytica*-specific antigen" (EHSA) from *E. histolytica*/*E. dispar*, and the Triage Parasite Panel (BIOSITE Diagnostics, San Diego, CA, USA), which detects a 29-kDa antigen from *E. histolytica*/*E. dispar* using an immune-chromatographic strip (118). Recently, an ELISA sandwich assay was developed using two mAbs raised against a spacer region of the Jacob2 lectin of *E. histolytica*, a protein of the cyst wall [47]. Notably, the mAbs only recognized the cysts of *E. histolytica* but did not recognize the cysts of *E. dispar* or *E. Bangladeshi* by immunofluorescence assays. The successful detection of cysts in formalin-fixed stool samples was observed, suggesting that the anti-Jacob2 mAbs could be used for the development of a diagnostic kit for *E. histolytica* infection in any type of stool sample.

Recently, several molecular diagnostic methods, including conventional and real-time polymerase chain reactions (PCRs), have been developed for the specific diagnosis of each of these three *Entamoeba* species in clinical laboratories. Currently, there is a great variety of PCR methods targeting different genes for the detection and differentiation of these amoebas [31,48]. The consistent genetic diversity detected in the small rRNA subunit (18SDNAr) of *E. histolytica* and *E. dispar* initiated the use of this gene as a target for the differentiation of the two species [49–53]. PCR techniques targeting this gene are 100 times more sensitive than the current best available enzyme immunoassay (ELISA) kit [54–56] and are widely used to distinguish these species since there are multiple copies of these genes in amoebas [57], which makes the 18SDNAr gene easier to detect than a DNA fragment from a single copy of a gene.

However, for a good result from the PCR, good-quality DNA is required, which is why extraction optimization is necessary. Recently, simple and effective methods for the isolation of *Entamoeba* DNA from feces have been developed. Commercially available DNA extraction kits are recommended due to their ease and success as they minimize extraction time, and the DNA can be extracted directly from the feces without the need to culture the parasite. The following kits have been used for the direct extraction of DNA from fecal samples include XTRAX DNA extraction kit [58] (Gull Laboratories, Salt Lake City, UT, USA), Extract Master Faecal DNA extraction kit Epicentre Biotechnologies, Madison, WI, USA), and the Genomic DNA Prep Plus kit [59]. Of the methods for DNA extraction, Qiagen kits have been used the most widely with the QIAamp stool kit now predominating. The QIAamp tissue kit spin columns (QIAGEN) have also been used for the extraction and purification of *Entamoeba* DNA from fecal samples [60]. Various modifications, including optimizing the duration and temperature of proteinase K digestion, adding additional wash steps, and treatment of the sample with 2% polyvinylpolypyrrolidone, have all been used [61,62]. The QIAamp stool kit has proven to be the most widely accepted method for DNA extraction providing successful and reliable recovery of DNA from fecal material [50,63,64]. Aspirated pus from ALA can also be tested by PCR and has shown excellent sensitivity and specificity [65,66].

4. Treatment and Prevention

Due to the different amoebiasis forms and severity of the symptoms, the treatment varies, and diverse drugs can be used. Regarding treatment, amoebiasis is usually treated by amebicides, which are prescribed depending on the severity of the infection [67].

Antiamoebics are the most recommended drugs; these are classified as (1) luminal amebicides which included paromomycin, diloxanide furoate, iodoquinol, and nitazoxanide; they act only on the intestinal lumen and are used to treat amoebic, not dysenteric, colitis, and (2) tissue amebicides such as chloroquine, emetine, tinidazole, and metronidazole, which are the elected treatment in patients with symptomatic intestinal amoebiasis, asymptomatic cyst carriers, and amoebic liver abscesses, due to their rapid intestinal absorption acting at the systemic level [15,68]. Metronidazole is the major drug used in invasive amoebiasis cases; although the toxicity and side effects of this compound are important, the most frequent side effects are nausea, vomiting, headaches, a metallic or bitter taste in the mouth, and some more serious effects such as anorexia, ataxia, and skin rashes/itching. Nevertheless, metronidazole is widely used in the treatment of invasive amoebiasis due to its efficiency and its low cost [69–71].

Likewise, the development of resistance has been reported in some anaerobic pathogens [72,73], but in our experience, there is no clear evidence of resistant strains of *E. histolytica* in patients with amoebic liver abscesses. However, it is important that after systemic treatment of invasive amoebiasis such as amoebic liver abscesses to prescribe a luminal antiamoebic treatment with the purpose of avoiding *E. histolytica*/*E. dispar* cysts luminal infection [15].

On the other hand, the primary measures for the prevention and control of amoebiasis infections remain hygiene habits, use of latrines, hand washing, improvement of water purification systems and adequate hygiene practices to prepare food, and the avoidance of fecal–oral exposure, which could all decrease disease incidence [74,75]. It seems easy to avoid amoebiasis infection by adopting these measures; however, these measures are unattainable when we talk about the fact that this infection is endemic in underdeveloped countries and in poor areas of these countries where the basic infrastructure is not available. Therefore, it is necessary that great efforts, on the part of governments and health systems, be directed to generate the conditions and infrastructure necessary to prevent and reduce the incidence of amoebiasis in developing countries.

Unfortunately, despite the efforts of the scientific community in the field, it has not been possible to obtain a vaccine against this disease so far. However, many recent vaccine development studies appear to be promising [20].

5. Pathogenesis

Pathogenesis of *E. histolytica* is multifactorial, since the virulent molecules of the parasite, as well as the host's immune response, play an important role in the pathogenesis of the disease, causing damage to tissues that facilitate entry to systemic sites [76]. The destructive mechanisms of *E. histolytica* include contact with target cells, cytolysis, and phagocytosis, and the degradation of ingested cells. After contact with trophozoites in the epithelium, the cells increase the paracellular permeability produced by the opening of the TJ junctions and the distortion of the microvilli [77]. Superficial blisters and tiny focal discontinuities appear in the host plasma membrane, displacing and separating neighboring cells and compromising membrane integrity [78].

Entamoeba histolytica usually lodges in the intestine and in about 90 percent of cases, it generates an asymptomatic infection; however, it is not clear why a minority of individuals infected with *E. histolytica* activate a pathogenic phenotype [79]. Throughout many years of study, the participation of pathogenic molecules involved in various causal events due to *E. histolytica* infection has been demonstrated. The most studied physiological events are: (1) the colonization of the intestinal mucus layer, (2) the adherence of trophozoites to the host intestinal epithelium, (3) the interaction with the intracellular junctions of the epithelium, (4) cytolysis, (5) phagocytosis and trogocytosis, (6) the activation of the host's immune response, and (7) the contributions of the host gut microbiota [4,78,80,81]

The genome sequence of *E. histolytica* strain HM1: IMSS was published and analyzed in 2005 [82–84]. The genome assembly contained 20, 800, and 560 bp of DNA in 1496 scaffolds. The genome had a high AT content (approximately 75%). Likewise, approximately half of the assembled sequence was predicted to be coding, with 8333 annotated genes [85]. Since it was sequenced in 2005, the genome of *E. histolytica* has been extensively analyzed due to its implications for human health [86].

These analyses of the *E. histolytica* genome have revealed a variety of metabolic adaptations, which include the reduction in or elimination of most mitochondrial metabolic pathways and the use of oxidative stress enzymes generally associated with anaerobic prokaryotes. Based on the knowledge of the *E. histolytica* genome there is evidence that suggests that cellular events such as meiotic recombination and the possible existence of a sexual reproduction mechanism have occurred in its chromosomes, which could allow the transfer of genetic information between different strains of *E. histolytica*, generating amoebas with a greater capacity to invade tissues and greater resistance to drugs, allowing them to survive in the host and even increase their capacity to survive outside it [87,88].

Another characteristic that has been observed in the *E. histolytica* genome is the so-called gain of genetic information, which includes the significant number of genes (at least 68) that seem to have been gained by horizontal transfer of bacterial genes from intestinal flora, some of them from the same donor group: alpha-1,2-mannosidase (EHI 009520), mannose-1-phosphate guanylyltransferase (EHI 052810), and fructokinase (EHI 054510) from Bacteroidetes; nicotinatephosphoribosyltransferase (EHI 023260) and hypothetical protein (EHI 072640) from Bacteroidales; and Fe-S cluster assembly protein NifU (EHI 049620) and metallo-beta-lactamase family protein (EHI 068560) from proteobacteria [82,84,89]. These genes tend to be involved in metabolic processes characteristic of the anaerobic lifestyle of the organisms [82]. Likewise, the analysis of the *E. histolytica* genome has also revealed that different genes encode proteins belonging to the A1G1 family, whose function is related to drug resistance in bacteria [90]. It has been observed that the expression of this group of proteins is strongly diminished in *E. dispar*; the previous study suggests that these molecules could participate directly in the virulence of the pathogenic amoebae [91]. Some genes that are important in the virulence of *E. histolytica* are genes that encode BspA-like proteins (BspA-like) that participate in cell aggregation by binding to extracellular matrix proteins and in adhesion to target cells; these functions are important for cellular damage and can also stimulate the production of proinflammatory cytokines through the stimulation of Toll-like receptors, which participate in the host innate immune response responsible for limiting tissue damage [92]. These cytokines are believed to help generate an inflammatory microenvironment that could favor the destruction of cells by amoebae [91]. The analysis of the *E. histolytica* genome has also made it possible to identify redundancy in genes that have been widely studied for their participation in different cellular processes related to the pathogenesis of *E. histolytica*. For example, the genes encoding the lectin Gal/GalNAc is important for the adhesion of trophozoites to epithelial cells; the genes that encode for proteins called amoebopores and some of the cysteine proteinases are involved in the cytolysis of epithelial cells [93]. Some of the molecules that have recently been identified, and the mechanisms involved in epigenetic modifications, such as DNA methylation or histone modification in *E. histolytica*, act directly in the conformation of chromatin and the regulation of gene expression [94]. These epigenetic regulatory mechanisms could be important to activate or prevent the expression of genes involved in virulence and cyst formation.

Another recent discovery in the study of the *E. histolytica* genome has been the presence of elements called transposons and retrotransposons, which constitute a significant portion of the genome of *E. histolytica* [95]. The insertion of transposons and retrotransposons results in changes in the amount of DNA, as well as changes and mutation genes. Although until now there is not much information about the function of this type of molecule, it is thought that these elements of amoebic DNA could be participating in the generation of pathogenic variants of *E. histolytica*, which are obtained from clinical isolates and cultured in the presence of pathogenic bacteria, in which there is an increase in the virulence of *E. histolytica*.

Another molecule that participates in *E. histolytica* infection is the cyclooxygenase from *E. histolytica* (EhCox). EhCox, derived from prostaglandin E2, stimulates the chemokine IL-8 from mucosal epithelial cells that recruit neutrophils to the site of infection, increasing the tissue damage. This phenomenon was verified by making gene silencing of EhCox (EhCoxgs) which increases the expression and production of endogenous cysteine protease (CP) and the virulence of trophozoites without altering CP gene transcripts. Shahi et al. propose a negative feedback mechanism in *E. histolytica* to limit proteolytic activity during colonization that can inadvertently trigger inflammation in the gut-enhanced erythrophagocytosis, cytopathic effects on colonic epithelial cells, and elicited proinflammatory cytokines in mice colonic loops, as well as increased inflammation associated with high levels of myeloperoxidase activity [76].

The sphingomyelinase enzymes encoded by *E. histolytica* are other molecules participating in the pathogenesis of three of the neutral sphingomyelinase enzymes encoded in the *E. histolytica* genome. In transfected trophozoites, an overexpression of EhnSM1 and EhnSM2 caused an increase in cytopathic activity and EhnSM3 induced an increase in hemolytic and cytotoxic activities. Another of the most important virulence molecules in *E. histolytica* is the amoebopore, which is a pore-forming protein. An increase in gene expression of amoebapores A, B, and C has been seen in virulent *E. histolytica* strains in comparison with less virulent *Entamoeba* species. Urquieta-Ramírez et al. [96] mention that in a *E. histolytica* strain that overexpresses neutral sphingomyelinases, the gene expression levels for cysteine proteinase 5, adhesin 112, and heavy and light Gal/GalNAc lectin subunits are not affected. They propose that the increase in the cytotoxic and lytic effect of EhnSM3 overexpressing strain can be related to the sum of the effect of EhnSM3 plus amoebapores in a process cell contact-dependent manner or as a mediator by inducing the gene expression of amoebapores enabling the link between EhnSM3 with the virulence phenotype of *E. histolytica*.

Efforts have also been made to elucidate the pathogenicity of *E. histolytica* from genomic studies. Wilson et al. [97] showed differences in the expansion and contraction of families of proteins associated with host or bacterial interactions and highlighted the importance to parasitic *Entamoeba* species of surface-bound proteins involved in adhesion to extracellular membranes, such as the Gal/GalNAc lectin and members of the BspA and Ariel1 families. On the other hand, Nakada-Tsukui et al. [98] find that the AIG1 family protein plays a pivotal role in *E. histolytica* virulence via the regulation of host cell adhesion.

The PTP superfamily is classified as classical tyrosine-specific phosphatases, dual-specificity phosphatases, cdc25 phosphatases, and low-molecular-weight protein tyrosine phosphatase (LMW-PTP) [99]. The genome of *E. histolytica* contains two genes codifying for LMW-PTPs, EhLMW-PTP1, and EhLMW-PTP2, which are identical to the amino acid sequence except for a single conservative residue change at position A85 V. Putative substrates have been identified using an EhLMW-PTP1 mutant at the catalytic site, suggesting it plays an essential role in parasite virulence [100]. Torres-Cifuentes et al. [101] analyzed the potential role of EhLMW-PTP2 in the virulence of *E. histolytica* and found a novel and unexpected effect on adhesion, phagocytosis, and cytopathic effect mediated by regulating the LMW-PTP2 mRNA and protein expression in transfected amoebas. They suggested that EhLMW-PTPs are essential enzymes that regulate cellular pathways activated in the parasite during infection.

On the other hand, it is known that iron is a determinant in the survival of *E. histolytica* and can modulate the expression of virulence factors. Some of the most representative events of the role of iron in the survival of *E. histolytica* are specified by Gastelum-Martínez et al. The most highly expressed virulence factors include EhCP1, EhCP2, EhCP3, and EhCP5. EhCP1-6 is overexpressed in limited iron conditions in culture. Negative regulation by iron was shown for Ehmmbp26 and Ehmmbp45, which obtain iron from the haem group [102]. Aldose reductase participates in siderophore biosynthesis and/or ROS formation. Superoxide dismutase (EhSOD) is responsible for the detoxification of superoxide radicals. Acetaldehyde/alcohol dehydrogenase-2 (EhADH2) is responsible for the internalization of human holo-transferrin. NADPH-dependent oxidoreductase (EhNO2) is involved in redox homeostasis through the reduction of L-cysteine and iron. Actin and genes related to the reorganization of the parasite cytoskeleton such as actobindin and cofilin are downregulated by iron [103]. The iron concentration could affect the cytoadherence capacity of the trophozoite. Acyl-CoA synthetase is involved in the catabolism of fatty acids. Cysteine synthase CS1 and CS2 and cysteine desulphurase (NifS) are involved in cysteine metabolism and possibly in the metabolism of sugar-containing amino acids, and both are upregulated by iron. S-adenosylmethionine synthetase (SAM) participates in the biosynthesis of SAM and many biosynthetic pathways including methionine-cysteine conversion and haem biosynthesis. SAM is downregulated by iron. The presence of cis-elements in mRNA (iron-responsive elements (IREs)) was demonstrated in the actin and Ehhmb26 genes, suggesting the presence of a post-transcriptional IRE/iron-responsive protein [IRP] iron regulatory system in this parasite.

During chronic inflammation, the vagus nerve limits the immune response through the anti-inflammatory reflex, which includes acetylcholine (ACh) as one of the predominant neurotransmitters at the infection site. Consequently, the response of *E. histolytica* trophozoites to ACh could be implicated in the establishment of invasive disease. Medina-Rosales et al. [104] evaluated the effect of ACh on *E. histolytica* virulence. They demonstrated that *E. histolytica* trophozoites bind ACh on their membrane and show a clear increase in the expression of virulence factors that were upregulated upon stimulation with the neurotransmitter. ACh treatment increased the expression of L220, Gal/GalNAc lectin heavy subunit (170 kDa), amoebapore C, cysteine proteinase 2 (ehcp-a2), and cysteine proteinase 5 (ehcp-a5). Moreover, erythrophagocytosis, cytotoxicity, and actin cytoskeleton remodeling were augmented after ACh treatment.

Lipids are essential in the cellular processes and pathogenesis of this organism *Entamoeba histolytica* has 27 putative enzymes involved in the lipid metabolic pathways and the trophozoites have mechanisms to synthesize or remodel phospholipids. They acquire cholesterol and fatty acids from the environment; thus, parasites need lipid scavenging from the host to regulate their cellular processes for survival or they may provoke disequilibrium in lipid synthesis and metabolism in the organism. However, lipid metabolism during host–pathogen interaction research is still an open field to be explored and exploited for the development of new methodologies for diagnosis and treatment [17].

6. Intestinal Ecosystem and *Entamoeba* Interactions

This is a very recent field of research and there are highly relevant findings on the interaction of *E. histolytica* in the colon with multiple components that modulate the invasion and destruction of tissues in the outer mucus layer [105]. In the colon, *E. histolytica* interacts with a diverse microbiota and takes advantage of its presence since it uses its decomposition products (such as glycans) that can serve as a source of nutrients, and at the same time, *E. histolytica* can feed on the colonic microbiota [105,106]. Recently, a metagenomics study on the in vitro association between *E. histolytica* and enteric bacteria showed that *E. histolytica* preferentially phagocytoses *Lactobacillus ruminus*, *Faecalibacterium prausnitzii*, *Bifidobacterium longum*, and *B. ruminantium*. These findings suggest that *E. histolytica* prefers to phagocytose commensal bacteria that are part of the healthy microbiota [106].

In addition to the predator–prey relationship, there is recent evidence that when the infection caused by *E. histolytica* is symptomatic, the intestinal microbiota could play an important role in the development of the disease [9,107]. Reyna-Fabian et al. examined samples aspirated from abscess material obtained from patients who were clinically diagnosed with amoebic liver abscesses (ALAs) or pyogenic liver abscesses (PLAs). They suggested that most of the ALAs or PLAs are mixed abscesses (bacteria and protozoa) and that the disease outcomes could be related to the bacterial/protozoan density ratio [35]. This is in line with Ximénez et al., 2010, who hypothesized that the size of intestinal amebic ulcers and the local inflammatory response permits the exit of *E. histolytica* trophozoites and intestinal bacteria, some of which enter the phagocytic vacuoles of trophozoites [27].

It has been determined in experimental models, that both the pathogenicity and virulence of *E. histolytica* are affected by the presence or absence of enteric bacteria and this could help explain why only about 10% of individuals infected with *E. histolytica* develop intestinal amoebiasis [105,108–110]. Evaluating the pathogenicity of *E. histolytica* with co-infection with other parasites has been reported in in vitro studies to show a twofold increase in CaCo monolayer destruction when *E. histolytica* interacted with enteropathogenic *Escherichia coli* (EPEC), but not with *E. coli* DH5α, for 2.5 h. This was associated with increased *E. histolytica* proteolytic activity as revealed by zymogram analysis and degradation of the *E. histolytica* CP-A1/5 (EhCP-A1/5) peptide substrate Z-Arg-Arg-pNC and EhCP4 substrate Z-Val-Val-Arg-AMC. Additionally, *E. histolytica*–EPEC interaction increased EhCP-A1, -A2, -A4, -A5, Hgl, Apa, and Cox-1 mRNA expression. In animal models of disease, the *E. histolytica*–EPEC interaction enhanced cellular inflammatory reaction, granuloma formation, and necrosis in ALA in hamsters and increased secretory and proinflammatory cytokine responses in closed colonic loops in mice [111].

Furthermore, Reyna-Fabian (2010) [35] showed that *E. dispar* in association with the gut microbiota could be potentially responsible for intestinal or liver tissue damage, like that observed in *E. histolytica*. More recently, Vilela da Silva et al. (2021) reported new evidence about some *E. dispar* strains in that the cysteine proteinase 5 expression in *E. dispar* MCR, VEJ, and ADO strains, isolated in Brazil, show that *S. typhimurium* and *E. dispar* co-infection worsens amoebic colitis, possibly by increasing the expression of amoebic virulence factors [112]. However, great effort is still required to elucidate the factors that drove these interactions relevant to the development of the disease caused by *E. dispar*.

On the other hand, important alterations in the intestinal microbiota composition have been observed due to infection by E. histolytica [9]. A dysbiotic state has been observed in linked E. histolytica-positive patients in India, characterized by a decrease in *Bacteroides*, *Clostridium coccoides*, *C. leptum*, *Lactobacillus*, *Campylobacter*, and *Eubacterium* with a corresponding increase in *Bifidobacterium* species [105,113]. Another recent study in Cameroon also linked the presence of *E. histolytica* with an increase in *Clostridial* and *Ruminococcaceae* and a corresponding decrease in *Prevotella copri* and *Fusobacteria* [114]. This study almost showed that in *E. histolytica*-infected individuals an augmented number of bacterial species (alpha diversity) and a decrease in interindividual variation (beta diversity) are evident. Also, it was recently demonstrated that a dysbiotic state renders the host hyper-responsive for increased proinflammatory cytokine and chemokine production with hypersecretory responses toward *E. histolytica* [105]. The authors mentioned that these findings are of great relevance, as individuals with dysbiosis (either by disease, antibiotics, or due to a poor diet) that are infected with *E. histolytica* are at a high risk of developing severe intestinal amoebiasis associated with acute inflammation, compared to individuals with a healthy microbiota. The fact that *E. histolytica* induces the production of antimicrobial peptides but is resistant to their cytopathic effect could explain the alteration in microbial composition observed in *E. histolytica* infections [115].

However, until now, it has been unknown whether the dysbiosis observed in amoebiasis is the cause or the effect of infection by *E. histolytica*, mainly in rural or suburban areas where the indiscriminate use of antibiotics can secondarily induce intestinal dysbiosis; therefore, interactions between *E. histolytica* and the microbiota are an interesting field of research.

7. Discussion and Future Perspectives

Although *E. histolytica* was discovered over 100 years ago, amoebiasis remains a major public health challenge around the world, especially in developing countries where a large segment of the population does not have easy access to standard sanitary conditions and, therefore, does not have good hygienic conditions, making strategies that minimize its transmission ineffective [4]. The only reservoir of *E. histolytica* is humans and the infection occurs through food, water, or hands contaminated with fecal matter that contains cysts. Therefore, it is necessary to develop government prevention and control programs of transmissibility, morbidity, and mortality caused by *E. histolytica* in endemic countries, which is a real challenge. Likewise, as mentioned in this review, person-to-person transmission also occurs through oral–genital and oral–anal contact, especially among the homosexual population, so it is necessary to implement informational strategies to avoid the transmissibility of the different forms of amoebiasis in this population.

Given the different ways amoebiasis can occur, it is important to have robust tests to help make an accurate diagnosis and overcome the limitations of the current diagnosis, especially in endemic areas, where individuals are constantly exposed to *E. histolytica*.

Advances in molecular diagnostic methodologies have been of great importance to recognize and differentiate *E. histolytica* from nonpathogenic *Entamoeba* species, and this differentiation has had a great impact on the epidemiology and clinical management of patients. However, although molecular detection is highly sensitive and specific and has the potential to be developed into field-applicable tests, the cost is still a barrier to their extensive usage as a routine laboratory test method in most endemic areas, where a correct diagnosis of amoebic infection is important to avoid morbidity, death, and disease transmission. As well, new strategies must include improving the potency of existing amebicides, discovering the new usage of approved drugs, drug rediscovery, and drug targeting of essential *E. histolytica* components to use in deworming campaigns, especially in endemic countries. Further research areas that need to be explored include the discovery of biomarkers that can predict individuals prone to symptomatic infection, distinguish between the different stages of infection, and monitor treatment success. In the same way, efforts should also be directed at studies that focus on the interactions of *E. histolytica* with microorganisms in the intestinal environment. This knowledge would have a positive impact on the clinical and laboratory diagnosis of diarrheal syndrome, its treatment, and, subsequently, the implementation of more reliable control schemes. Additionally, more research will be needed to understand the relationship between the commensal microbiota and the immune response in this parasite infection. Likewise, the advance in molecular techniques could be an important tool in the study of the geographic distribution of species of *Entamoeba* and could determine the morbidity rates of different forms of amoebic infection in different geographic areas. Although the analysis of the *Entamoeba* genomes has shed light on the study of these parasites, more research is still needed to understand, in more detail, the evolutive history of these microorganisms, in particular *E. histolytica*. In conclusion, understanding the epidemiology, pathology, and molecular biology of this parasite will not only lead to the improvement of diagnostic and treatment options but also, ultimately, to the development of safe and efficacious vaccines for the control of the disease. Finally, and no less important, the improvement of water purification systems and hygiene practices can greatly decrease disease incidence; however, it requires considerable time, changes, and monetary investments.

Author Contributions: P.M., A.S.-V. and C.X. conceptualized the review content and wrote the first draft of the manuscript. L.R.-V., E.G., H.P.-J., T.P.-B. and M.R. edited the manuscript. E.G.H., M.d.l.A.P. and M.E.Z. participated in specific paragraphs and re-reading the text. All authors contributed to the revision of the manuscript. All authors have read and agreed to the published version of the manuscript.

Funding: The present work was supported by Grants from PAPIIT IN217821 and IN200420 (DGAPA), Universidad Nacional Autónoma de México (UNAM). CONACyT-Salud 272601 S008-Fonsec SSA/IMSS/ISSSTE.

Institutional Review Board Statement: Not applicable.

Informed Consent Statement: Not applicable.

Data Availability Statement: Not applicable.

Acknowledgments: The authors highly appreciate Miriam Nieves-Ramírez for her assistance in the pathogenesis section of the manuscript. H.P.-J. received a research grant from the Postdoctoral Stays in Mexico, program-CONACyT, for his postdoctoral stay (CVU 408467).

Conflicts of Interest: The authors declare no conflict of interest.

Ascaris suum draft genome

Aaron R. Jex[1]*, Shiping Liu[2]*, Bo Li[2]*, Neil D. Young[1]*, Ross S. Hall[1], Yingrui Li[2], Linfeng Yang[2], Na Zeng[2], Xun Xu[2], Zijun Xiong[2], Fangyuan Chen[2], Xuan Wu[2], Guojie Zhang[2], Xiaodong Fang[2], Yi Kang[2], Garry A. Anderson[1], Todd W. Harris[3], Bronwyn E. Campbell[1], Johnny Vlaminck[4], Tao Wang[4], Cinzia Cantacessi[1], Erich M. Schwarz[5], Shoba Ranganathan[6], Peter Geldhof[4], Peter Nejsum[7], Paul W. Sternberg[5], Huanming Yang[2], Jun Wang[2], Jian Wang[2] & Robin B. Gasser[1]

Parasitic diseases have a devastating, long-term impact on human health, welfare and food production worldwide. More than two billion people are infected with geohelminths, including the roundworms *Ascaris* (common roundworm), *Necator* and *Ancylostoma* (hookworms), and *Trichuris* (whipworm), mainly in developing or impoverished nations of Asia, Africa and Latin America[1]. In humans, the diseases caused by these parasites result in about 135,000 deaths annually, with a global burden comparable with that of malaria or tuberculosis in disability-adjusted life years[1]. *Ascaris* alone infects around 1.2 billion people and, in children, causes nutritional deficiency, impaired physical and cognitive development and, in severe cases, death[2]. *Ascaris* also causes major production losses in pigs owing to reduced growth, failure to thrive and mortality[2]. The *Ascaris*–swine model makes it possible to study the parasite, its relationship with the host, and ascariasis at the molecular level. To enable such molecular studies, we report the 273 megabase draft genome of *Ascaris suum* and compare it with other nematode genomes. This genome has low repeat content (4.4%) and encodes about 18,500 protein-coding genes. Notably, the *A. suum* secretome (about 750 molecules) is rich in peptidases linked to the penetration and degradation of host tissues, and an assemblage of molecules likely to modulate or evade host immune responses. This genome provides a comprehensive resource to the scientific community and underpins the development of new and urgently needed interventions (drugs, vaccines and diagnostic tests) against ascariasis and other nematodiases.

We sequenced the *A. suum* genome at ~80-fold coverage (Supplementary Fig. 1), producing a final draft assembly of 272,782,664 base pairs (bp) (N50 = 407 kilobases, kb; N90 = 80 kb; 1,618 contigs of >2 kb) (Table 1) with a mean GC-content of 37.9%. This genome has few repetitive sequences (about 4.4% of the total assembly) relative to that reported for other metazoan genomes sequenced to date[3–6], probably as a result of chromatin diminution[7]. We identified 424 distinct retrotransposon sequences (see Supplementary Tables 1–3) representing at least 22 families (8 long terminal repeats (LTRs), 12 long interspersed elements (LINEs) and 2 short interspersed elements (SINEs)), with *Gypsy*, *Pao* and *Copia* classes predominating for LTRs ($n = 97$, 85 and 60, respectively) and CR1, L1, and reverse transcriptase encoding RTE-RTE classes predominating for non-LTRs ($n = 29$, 28 and 21, respectively). We also identified eight families of DNA transposons (91 distinct sequences in total), of which *MuDr*, *En-Spm* and *Merlin* ($n = 12$, 9 and 8, respectively) predominated. We predicted 18,542 genes (14,783 supported by transcriptomic data), with a mean total length of 6.5 kb, exon length of 153 bp and a mean of 6.4 exons per gene (see Supplementary Fig. 2). Compared with the nematodes (roundworms) *Caenorhabditis elegans*[3], *Pristionchus pacificus*[8], *Brugia malayi*[9] or *Meloidogyne hapla*[10], overall, the *A. suum* genes are significantly longer (see Supplementary Table 2), relating primarily to expansions of intronic regions (mean 1.1 kb).

Table 1 | Features of the *Ascaris suum* draft genome

Estimated genome size in megabases	309
Total number of base pairs within assembled scaffolds	272,782,664
N50 length in bp; total number >2 kb in length	407,899; 1,618
N90 length in bp; total number >N90 length	80,017; 748
GC content of whole genome (%)	37.9
Repetitive sequences (%)	4.4
Proportion of genome that is coding (exonic; including introns) (%)	5.9; 44.2
Number of putative coding genes	18,542
Gene size (mean bp)	6,536
Average coding domain length (mean bp)	983
Average exon number per gene (mean)	6
Gene exon length (mean bp)	153
Gene intron length (mean bp)	1,081
GC content in coding regions (%)	45
Number of transfer RNAs	255

N50 means 50% of all nucleotides in the assembly are within contigs of ≥408 kb. N90 means 90% of all nucleotides in the assembly are within contigs of ≥80 kb. Genome size estimated on the basis of *k*-mer (see online-only Methods) frequency.

Most (78.2%) of the predicted *A. suum* genes (Fig. 1) have a homologue (BLASTp cut-off $\leq 10^{-5}$) either in *C. elegans* ($n = 12{,}779$; 68.9%), *B. malayi* (12,853; 69.3%), *M. hapla* (10,482; 56.5%) or *P. pacificus* (11,865; 64.0%), with 8,967 being homologous among all species examined, and 4,042 (21.8%) being 'unique' to *A. suum* (see Fig. 1). Of the genes with homology to *C. elegans* or *B. malayi*, ~50%

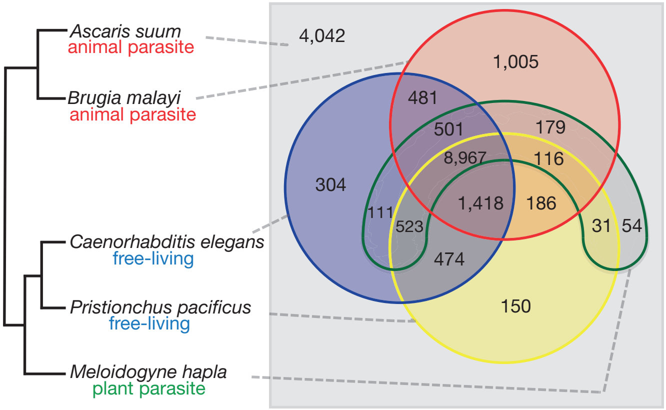

Figure 1 | Venn diagram summarizing the overlapping homology between the *Ascaris suum* gene set and those of other nematodes. Grey box (right) represents genes unique to *A. suum*, relative to *Brugia malayi* (red circle), *Caenorhabditis elegans* (blue circle), *Meloidogyne hapla* (green arc) and/or *Pristionchus pacificus* (yellow circle). The phylogram (left) displays the evolutionary relationships currently proposed among the nematodes.

and 44%, respectively, were determined to represent one-to-one orthologues[11] (see Supplementary Data 1). For these orthologues (on scaffolds exceeding one megabase, 1 Mb, in size), we explored synteny for *A. suum* and *B. malayi* by pairwise comparison with *C. elegans* (see Supplementary Data 1). The findings show that interchromosomal gene rearrangements in *A. suum* are relatively rare and occurred less frequently in *A. suum* than in *B. malayi*[9] relative to *C. elegans* since their evolutionary divergence[12]. In contrast, intrachromosomal rearrangements were relatively common and comparable in frequency to those inferred for *B. malayi*[9]. Overall synteny was significantly higher between *A. suum* and *B. malayi* (∼15%) than between either species and *C. elegans* (∼3%), which is consistent with current knowledge of the evolutionary relationships among these three species[12]. Interestingly, of these *C. elegans* orthologous genes, 532 and 483 were exclusive to the current assemblies of the *A. suum* and *B. malayi* genomes, respectively (Supplementary Data 2). Although there were no homology matches between these two exclusive subsets of orthologues, they shared striking similarity in functional ontology (biological process), being linked predominantly to growth, reproduction, development and/or morphogenesis. There is clear evidence of plasticity in the germline of metazoans[13], with cases of products from non-homologous genes in different species having analogous function(s). Therefore, we hypothesize that these two unique gene subsets relate to differences in reproductive biology (oviparity versus viviparity) and life history (direct versus indirect) between *A. suum* and *B. malayi*. Clearly, this proposal warrants testing and functional validation in *C. elegans* and/or in *Ascaris*.

Of the entire *A. suum* gene set, 2,370 genes had an orthologue (BLASTp cut-off $\leq 10^{-5}$) belonging to one of 279 known biological (KEGG; see online-only Methods) pathways (Supplementary Data 3). Mapping to pathways in *C. elegans* indicated a full complement of molecules; by inference, the vast majority (95%) of the *A. suum* euchromatin is represented in the present genomic assembly, an inference that is supported by our transcriptomic data (Supplementary Tables 4 and 5). We were able to assign possible functions (such as for enzymes, receptors, channels and transporters; Supplementary Fig. 3, Supplementary Table 6 and Supplementary Data 4) to 13,503 (72.8%) of the genes predicted for *A. suum* (Fig. 2). For these genes, we predicted 456 peptidases belonging to five major classes (aspartic, cysteine, metallo-, serine and threonine), with the metallo- ($n = 184$: 41.0%) and serine proteases ($n = 132$: 30.0%) predominating (Supplementary Data 4). Notably, the secreted peptidases (such as the M12 'astacins', the S9 and S33 serine proteases, and the C1 and C2 cysteine proteases) are abundantly represented, and have key roles in tissue invasion and degradation (for example, during migration and/or feeding) and/or immune evasion/modulation in many parasites[14,15].

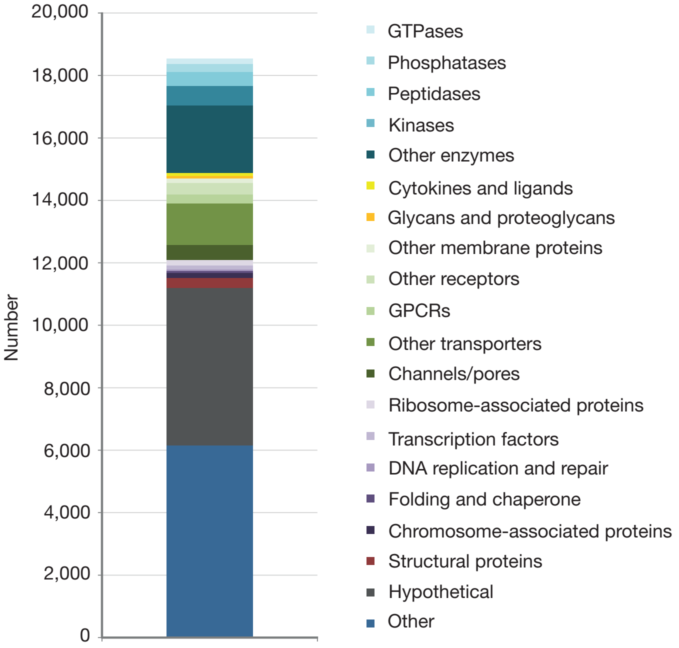

Figure 2 | The major protein classes representing the *Ascaris suum* gene set.

In addition, we identified 609 kinases and 257 phosphatases, respectively (Supplementary Data 4). All major classes of kinases are represented, with the tyrosine (TK: $n = 94$), casein (CK1: $n = 83$), CMGC ($n = 67$) and CAMK ($n = 54$) being most abundant in *A. suum*. The phosphatome includes 17 receptor and 68 conventional tyrosine, 64 serine/threonine and 39 dual-specificity phosphatases. On the basis of homology with molecules in *C. elegans*, 169 GTPases are encoded in the *A. suum* genome, including 135 small GTPases (Ras superfamily) representing the Rab ($n = 36$), Ras ($n = 35$; plus 8 Ras-like), Rho ($n = 17$; plus 9 Rho-like) or Ran ($n = 6$) subfamilies. Examples of these homologues include *eft-1*, *fzo-1*, *glo-1* and *rho-1*, which have essential roles in embryonic, larval and/or reproductive development (see www.wormbase.org).

Given their key roles, many of these enzymes are proposed as targets for anti-parasitic compounds and/or vaccines[16–18]. Equally, the range of receptor and channel proteins identified here are interesting because many common anthelmintics bind such targets[19]. Here, we predicted 279 G protein-coupled receptors (GPCRs) for *A. suum* and 477 channel or pore proteins (Supplementary Data 4), including 272 voltage-gated and 98 ligand-gated ion channels. Many voltage-gated ion channels are known targets for nematocidal drugs, such as macrocyclic lactones (for example, ivermectin) and levamisole, and an aminoacetonitrile derivative, monepantel, is the most recent example of a highly effective nematocide that binds to a ligand-gated ion channel[19]. Importantly, in the *A. suum* gene set, we found a homologue (*acr-23*) of the *C. elegans* monepantel receptor[19], suggesting that this drug may kill *A. suum*. In addition, we detected 462 transporters (for example, small molecule porter proteins), of which the major facilitator ($n = 155$), cation symporter ($n = 71$) and resistance-nodulation-cell division ($n = 56$) superfamilies were most abundant (Supplementary Data 4).

Excretory/secretory (E/S) peptides are central to understanding parasite–host interactions. We predicted the secretome of *A. suum* to comprise 775 proteins with diverse functions (Supplementary Data 5). Notable among them are 68 secreted proteases, including 20 SC clan serine proteases (S9 and S33 families), 18 MA clan metallo-proteases (M10, M12 and M41 families) and 5 CA/CD clan cysteine proteases (C1 and C13 families); see http://merops.sanger.ac.uk/ for clan definitions.

Secreted proteases have known roles in host-tissue degradation, required for feeding, tissue-penetration and/or larval migration for a range of helminths[14], including *Ascaris*[2]. In addition, they are involved in inducing and modulating host immune responses against parasitic helminths[15], which are often Th2-biased[20]. From the current understanding of these responses[15], we compiled a comprehensive list of *A. suum* E/S proteins homologous to helminth-secreted peptides with important immunogenic or immunomodulatory roles in host animals (Supplementary Table 7 and Supplementary Data 6). Such homologues represent about half of the predicted *A. suum* secretome. Most abundant among them are O-linked glycosylated proteins ($n = 300$), many of which are heavily targeted by immunoglobulin (Ig) M antibodies and bound by various pattern recognition receptors associated with host dendritic cells responsible for the induction of a Th2 immune response[15].

Other members of the *A. suum* secretome are predicted to direct or evade immune responses. These peptides include a close homologue of the E/S-62 leucyl aminopeptidase of the filarioid nematode *Acanthocheilonema viteae*, which has been shown to inhibit B-cell, T-cell and mast cell proliferation/responses, promote an alternative activation of the host macrophages, through the inhibition of the Toll-like receptor signalling pathway, and induce a Th2 response through

©2011 Macmillan Publishers Limited. All rights reserved

the inhibition of IL-12p70 production by dendritic cells[15]. Additional, immunomodulatory molecules predicted for *A. suum* (BLASTp cut-off $\leq 10^{-5}$) include homologues of another B-cell inhibitor (that is, the *B. malayi* cystatin CPI-2), several TGF-β and macrophage initiation factor mimics, numerous neutrophil inhibitors, various oxidoreductases, and five close homologues of platelet anti-inflammatory factor α (ref. 15). Some *A. suum* E/S peptides are predicted to be involved in immune evasion; for instance, some mask parasite antigens by mimicking host molecules (such as several C-type lectins with close homology to vertebrate macrophage mannose or CD23 (low affinity IgE receptors[15]).

Taken together, these data indicate that *A. suum* has a large arsenal of E/S proteins that are likely to be involved directly in manipulating, blocking and/or evading immune responses in the host. Understanding the immunomolecular interplay between *A. suum* and its host, early in infection, particularly during hepatopulmonary migration, should pave the way for designing prophylactic interventions, such as vaccination.

Ascaris larvae undertake an extensive migration through their host's body before they establish as adults in the small intestine. Following the ingestion of infective eggs and their gastric passage, third-stage larvae (L3s)[21] hatch from eggs in the gut and penetrate the intestinal wall; they then undergo, via the bloodstream, an arduous hepatopulmonary migration. The complexity of this migration coincides with important developmental changes in the nematode[2]. Clearly, this migration requires tightly regulated transcriptional changes in the parasite. We explored this aspect by characterizing the transcription profiles of infective L3s (from eggs), L3s from the liver or lungs of the host, and fourth-stage larvae (L4s) from the small intestine (Supplementary Fig. 4, Supplementary Data 7). Notable among genes enriched during larval migration are various secreted peptidases linked to tissue-penetration and degradation during feeding and/or migration[14], including three C1/C2, five M1, eight M12, fourteen S9 and five S33 clan members. Considering the complex nature of larval migration, a key role for molecules associated with chemosensory pathways is highly likely. Such molecules have been studied extensively in *C. elegans*[22], with numerous homologues being identified here in larval transcripts (Supplementary Data 7). With few exceptions, all of these homologues relate to olfactory chemosensation of volatile compounds (for example, alcohols, aldehydes or ketones), suggesting that the olfactory detection of molecular gradients is central to the navigation of *A. suum* larvae during migration. Lastly, considering the substantial host attack against migrating *Ascaris* larvae, E/S proteins probably play crucial roles in immune modulation and/or evasion during hepatopulmonary migration. Many such genes, including *Bm-alt-1*, *Bm-cpi-2* and *mif-4*, are highly transcribed in *A. suum* larvae (see Supplementary Data 7), particularly in migrating L3s.

Because of the large size of the adult nematode (10–15 cm), we were able to explore transcription in the musculature and reproductive tracts of adult male and female *A. suum* individuals as well (Supplementary Fig. 5 and Supplementary Data 8). Among the male-enriched transcripts is a range of genes associated specifically with sperm and/or spermatogenesis, including *fer-1*, *spe-4*, *spe-6*, *spe-9*, *spe-10*, *spe-15* and *spe-41*, *alg-4* and *msp-57* (see www.wormbase.org). Notable among the female-enriched transcripts is a large variety of genes associated with oogenesis/egg-laying (such as *cat-1*, *unc-54*, *cbd-1* and *pqn-74*), vulval development (such as *noah-1*, *nhr-25*, *cog-1* and *pax-3*) and/or embryogenesis (such as *cam-1* and *unc-6*; see www.wormbase.org). Although the functions of these genes have been explored in *C. elegans* (primarily a hermaphroditic nematode), this detailed insight into the tissue-specific transcription for a dioecious nematode is a major advance.

Analyses of these RNA-seq data revealed 163,777 single nucleotide polymorphisms (SNPs) in coding regions of the *A. suum* genome; 61% of them were synonymous, 7% non-synonymous and <0.1% termination codons (Supplementary Data 9). Some of the most variable genes in *A. suum* encoded ribosomal proteins ($n = 44$), translation initiation factor (*tif*) eIF-3 subunits 3 and 5, *tif* TFIIH subunit H2 and *tif* IF-2, galectin-4 and galectin-9, the latter two of which are probably linked to immune evasion[15] and may indicate that antigenic variation is among the many strategies apparent in *Ascaris* to combat the host immune response. Interestingly, the high nucleotide variability linked to the key elements of translation machinery did not relate to a bias in synonymous SNPs, suggesting that many mutations accumulate in particular 'hotspots' and/or are tolerated, but do not compromise either the structure or the function of this machinery. The least variable genes encoded various (druggable)[16,17] serine/threonine phosphatases ($n = 17$) as well as numerous receptors, channels and transporters, for which there was an unusually strong bias towards synonymous SNPs, reinforcing their potential as intervention targets.

Given our present reliance on a small number of drugs (for example, piperazine, pyrantel, albendazole and mebendazole) for the treatment of ascariasis, their repeated or excessive use might lead to resistance in *Ascaris* populations to some or all of these compounds[23]. As few new anthelmintics (that is, aminoacetylnitriles[19] and cyclooctodepsipeptides[24]) have been discovered in the past two decades using traditional screening methods, an effective, alternative means of drug discovery is urgently needed[23]. Genome-guided drug target or drug discovery has major potential to complement conventional screening and re-purposing. The goal of genome-guided analysis is to identify genes or molecules whose inactivation by one or more drugs will selectively kill parasites but not harm their host.

Because most parasitic nematodes are difficult to produce or maintain outside of their host, or to subject to gene-specific silencing by RNAi[23] or morpholinos[25,26], direct functional assessment of essentiality (that is, they are needed for the nematode's survival) is not yet practical. However, essentiality can be inferred from functional information for model organisms (for example, lethality in *C. elegans* and *D. melanogaster*)[27], and this approach has indeed yielded effective targets for nematocides[16]. In *Ascaris*, we identified 629 proteins (Supplementary Data 10) with essential homologues in *C. elegans* and *D. melanogaster* (linked to lethal phenotypes upon gene perturbation). Among these are 87 channels or transporters (including 44 voltage-gated ion channels), which represent protein classes most successfully targeted for anthelmintic compounds, including macrocyclic lactones, levamisoles and aminoacetonitrile

Table 2 | Druggable candidates in the *Ascaris suum* draft genome

Protein or chokepoint	Subtype (number of molecules)	Total number
GTPase	Small GTPase (22); Ras (13); Rab (5); Rho (3); Ras-like (1); others (2)	46
Kinase	TK (8); AGC (3); CAMK (2); TKL (2); STE (1); other (1)	17
Peptidase	A22A (5); M14B (3); M12B (2); M67A (1); C14A (1); C50 (1); M12A (1); M13 (1); T01A (1); C46 (1); S33 (1)	19
Phosphatase	STP (28); cPTP (4); DSP (3)	35
Transporters and channels	Channels and pores (30); primary active transporters (24); incompletely characterized transport system proteins (22); accessory factors involved in transport (5); electrochemical potential-driven transporters (5); group translocators (1)	87
'Lethal' chokepoints	CDP-diacylglycerol-inositol 3-phosphatidyltransferase	1
	G protein-coupled receptor kinase 5	1
	Phosphoribosylformylglycinamidine synthase	1
	Inosine-5′-monophosphate dehydrogenase	1
	Phospho-*N*-acetylmuramoyl pentapeptide transferase	1

Candidates were inferred from essentiality prediction and metabolic chokepoint analysis.

derivatives[19,28]. Also notable are 46 GTPases, 35 phosphatases (including PP1 and PP2A homologues, as targets for norcantharidin analogues)[16], 17 kinases and 19 peptidases (Table 2).

In addition to essentiality-based prediction, an alternative strategy has been to infer enzymatic chokepoints intrinsic to the complete metabolome of a parasite[29]. Such chokepoints are defined as enzymatic reactions that uniquely produce and/or consume a molecular compound, using the strategy that the disruption of such enzymes would lead to the toxic build-up (that is, for unique substrates) or starvation (that is, for unique products) of metabolites within cells. Pathway analysis identified 225 likely chokepoints linked to genes predicted to be essential in *A. suum* (Supplementary Data 10). We gave the highest priority to targets predicted from single-copy genes in the *A. suum* genome, reasoning that lower allelic variability would exist within populations and would thus be less likely to give rise to drug resistance.

Using this strategy, we identified five high-priority drug targets for *A. suum* (see Table 2 and Supplementary Data 10) that, given their conservation with *C. elegans* and *D. melanogaster*, are likely to be relevant in relation to many other parasitic helminths. Conspicuous among them is IMP dehydrogenase (GMP reductase), which has a variety of inhibitors (for example, mycophenolic acid analogues[30]) that could be tested for ascaricidal effects. Clearly, the druggable genome of *Ascaris* now provides a solid basis for rational drug design, aimed at controlling parasitic nematodes of major socioeconomic impact worldwide.

In conclusion, we have characterized the genome of *A. suum*, a major parasite of one of the world's most important food animals (pig) and the closest relative of *A. lumbricoides*, which infects about 1.2 billion people globally[1,2]. Intriguingly, the present *A. suum* draft genome exhibits unusually low repeat content and lacks Tas2 transposons[7]. These characteristics probably relate to the chromatin diminution described previously for some ascaridoids[7], indicating that our assembly represents the somatic genome of this parasite. The precise mechanism governing this diminution is not yet understood. Although the chromatin lost during this process is not fully characterized, there appears to be a significant loss in repeat content[7], consistent with the present assembly. Notably, the present gene set inferred for *A. suum* includes *fert-1* and *rpS19G*, which, although originally proposed to be germline-specific[7], were transcribed in all adult libraries sequenced here. This finding suggests that the genomic content lost during diminution might vary among individuals or tissues, and is a stimulus to investigate chromatin diminution between and among individual cells (that is, sperm or eggs), stages and tissue types of *A. suum*. Importantly, the present study, showing that a high-quality genomic assembly can be achieved using an approach based on whole-genome amplification, provides unique prospects for exploring diminution in detail, using the present genome as a reference.

In addition, our sequencing effort has characterized a broad range of key classes of molecules of major relevance to understanding the molecular biology of *A. suum* and the exquisite complexities of the host–parasite interplay on an immunobiological level. This work paves the way for future fundamental molecular explorations and the design of new methods for the treatment and control of one of the world's most important parasitic nematodes. This focus is now crucial, given the major impact of *Ascaris* and other soil-transmitted helminths, which affect billions of people and animals worldwide. Although these parasites are seriously neglected, genomic and post-genomic approaches provide new hope for the discovery of intervention strategies, with major implications for improving global health.

METHODS SUMMARY

We sequenced the genome of *A. suum* using Illumina technology from genomic DNA from the reproductive tract of a single adult female. From six paired-end sequencing libraries (insert sizes: 0.17 kb to 10 kb; see Supplementary Tables 1 and 2), we generated 39 Gb of useable short-read sequence data, equating to ~80-fold coverage of the 273-Mb genome. We assembled the short reads, constructed scaffolds in a step-by-step manner, and then closed intra-scaffold gaps[5]. Transposable elements, non-coding RNAs and the protein-coding gene set were inferred using a combination of predictive modelling and a homology-based approach. Orthology and synteny analyses were conducted using established methods[9,11]. We sequenced messenger RNA from infective L3s (from eggs), migrating L3s from the liver or lungs of the host, and L4s from the small intestine, as well as muscle and reproductive tissues from adult male and female *A. suum*, and used these data to aid gene predictions, define SNPs and explore key molecules associated with larval migration, reproduction and development. All proteins predicted from the gene set were annotated using databases for conserved protein domains, gene ontology annotations and model organisms (that is, *Caenorhabditis elegans*, *Drosophila melanogaster* and *Mus musculus*). Essentiality and drug target predictions were conducted using established or in-house methods.

METHODS

Sample procurement, preparation and storage. All specimens of *A. suum* were collected from pigs (*Sus scofra*) with naturally acquired infections in Victoria, Australia (adult nematodes) and Ghent, Belgium (larval stages). L3s and L4s were also collected from the liver or lung and from the small intestine, respectively, of pigs, using established procedures[31,32]. Nematodes were washed extensively in sterile physiological saline (37 °C), snap-frozen in liquid nitrogen and then stored at −70 °C until use.

DNA isolation, sequencing and quality control. Total genomic DNA was isolated from the reproductive tract of a single adult female of *A. suum* using a sodium-dodecyl sulphate/proteinase K digestion[33] followed by phenol-chloroform extraction and ethanol precipitation[34]. Total DNA yield was determined using the Qubit fluorometer double-stranded DNA HS Kit (Invitrogen). DNA integrity was verified with a 2100 Bioanalyser (Agilent). Short-insert (170 bp and 500 bp) and mate-pair (800 bp, 2 kb, 5 kb and 10 kb) genomic DNA libraries were prepared and paired-end sequenced using TruSeq chemistry on a HiSeq 2000 (Illumina). Whole-genome amplification, employing the REPLI-g Midi Kit (Qiagen), was used to produce (from 200 ng of genomic template) the required amount of DNA for the construction of the 2-kb, 5-kb and 10-kb libraries (Supplementary Fig. 6). The sequence data generated from each of the six libraries were verified, and low-quality sequences, base-calling duplicates and adapters removed. The size of the genome and the heterozygosity rate were estimated by establishing the frequency of occurrence of each 17-bp *k*-mer (a unique sequence of *k* (that is, 17) nucleotides in length) within the genomic sequence data set (from the 170-bp library) using an established method[5]. Genome size was estimated using a modification of the Lander–Waterman algorithm[35], where the haploid genome length in base pairs is $G = (N \times (L - K + 1) - B)/D$, where N is the read length sequenced in base pairs, L is the mean length of sequence reads, K is the *k*-mer length (17 bp) and B is the number of *k*-mers occurring less than four times (Supplementary Fig. 7). Heterozygosity was evaluated throughout the genome assembly by assessing the distribution of the *k*-mer frequency in the sequence data set.

RNA isolation, sequencing and assembly. We obtained total RNAs from egg-L3s ($n \approx 500{,}000$), liver-L3s ($n \approx 60{,}000$), lung-L3s ($n \approx 80{,}000$) or L4s ($n \approx 30{,}000$) and from the somatic musculature or reproductive tract of each of two adult male and two adult female *A. suum* using the TriPure reagent (Roche), and both yield and quality were verified by 2100 BioAnalyser (Agilent). Polyadenylated (polyA+) RNA was purified from 10 μg of total RNA using Sera-mag oligo(dT) beads, fragmented to a size of 300–500 bp, reverse-transcribed using random hexamers, end-repaired and adaptor-ligated, according to the manufacturer's protocol (Illumina). Ligated products of ~400 bp were excised from agarose and then PCR-amplified (15 cycles), as recommended. Products were purified over a MinElute column (Qiagen) and subjected to paired-end RNA-seq using TruSeq chemistry on a HiSeq 2000 (Illumina) and assessed for quality and adaptor sequence. Transcripts were assembled from RNA-seq data using Oases[36]. All transcripts were used to assess the completeness of the genome assembly and to predict genes.

Genomic assembly and quality control. Following sequencing, all DNA-sequence reads were corrected based on *k*-mer (=17) distribution[5]. Briefly, sequence reads were removed if >10% of bases were ambiguous (represented by the letter N) or multiple adenosine monophosphates (poly-A), and all remaining reads were filtered on the basis of Phred quality. For small insert-size libraries (that is, <800 bp), additional reads were removed from the final data set if >65% of bases were of a low Phred quality (<8). For large insert libraries (2 kb, 5 kb and 10 kb), reads were removed from the final data set if >80% of bases were of a low Phred quality (<8). Duplicate (that is, identical) reads and partial reads representing the Illumina adaptor sequence were also removed, as were reads from the 500-bp library representing paired reads found to overlap by >10 bp (allowing for a 10% mismatch). Corrected and filtered data were assembled into contigs using SOAPdenovo[5], and joined iteratively into scaffolds using a step-wise process (see Supplementary Fig. 8), using the paired reads generated from each library; local assemblies were used to close all gaps. Each nucleotide position in the final assembly was assessed for accuracy by aligning all filtered reads to the scaffolds using SOAP2aligner[37], allowing for up to five mismatches per read. The depth of coverage and repeat content were assessed initially by sliding-window analysis and presented as a frequency distribution (Supplementary Fig. 9). GC-content was estimated using 10-kb non-overlapping sliding windows, and GC-bias[38] was assessed based on a frequency distribution of these data (Supplementary Fig. 10). To assess the completeness of the genome assembly, RNA-seq data representing each of the organs (that is, musculature and reproductive tract), genders and/or stages of *A. suum* sequenced were mapped to the final assembly using the BLAST-like Alignment Tool (BLAT)[39].

Assessment of repeat content and annotation of non-coding RNA. Following genome assembly, tandem repeats were identified using the Tandem Repeats Finder program[40]. Transposable elements were predicted using a combination of homology-based comparisons (using RepeatMasker[41]) and *de novo* approaches (using LTR_FINDER[42], PILER[43] and RepeatScout[44]), with a consensus population of predicted repetitive elements, constructed in RepeatScout using fit-preferred alignment scores. Low-frequency repeats (≤25) and multi-copy genes (in the repeat element library) were filtered using RepeatMasker, producing a non-redundant sequence file, which was then used to identify and classify additional homologous repeats in the genome.

Gene prediction, and synteny and genetic variation analysis. The *A. suum* protein-coding gene set was inferred using *de novo*-, homology- and evidence-based (that is, transcriptomic) approaches. *De novo* gene prediction was performed on a repeat-masked genome using three programs (Augustus, GlimmerHMM and SNAP)[5]; training models were generated from a subset of the transcriptomic data set representing 1,355 distinct genes. Homology-based prediction was conducted by comparison with complete genomic data for *Caenorhabditis elegans*[3], *Pristionchus pacificus*[8] and *Brugia malayi*[9] using a multi-phase strategy, in which (1) all putative homologous gene sequences were preliminarily identified from alignments with protein sequences representing the complete gene set of each of the reference genomes (the longest transcripts were chosen to represent each gene) by TblastN (*e*-value cut-off: 10^{-5}) and grouped into gene-like structures using genBlastA[45]; (2) regions representing these putative genes, and flanking regions (3,000 bp) at the 5′- and 3′-ends of each predicted gene, were extracted from the assembly and aligned to the 'parent' sequences derived from the reference genomes using Genewise[46]; (3) all single-exon genes predicted to have arisen from a retro-transposition and containing at least one frame-shift error or representing incomplete coding domains of <150 bp as well as all multi-exon genes containing more than two frame-shift errors and/or representing incomplete coding domains of <100 bp, were discarded. Evidence-based gene prediction was conducted by aligning all RNA-seq data generated herein against the assembled genome using TopHat[47], with cDNAs predicted from the resultant data using Cufflinks[48]. Following the prediction of genes, a non-redundant gene set representing homology-based, *de-novo*-predicted and RNA-seq-supported genes, was generated using Glean (http://sourceforge.net/projects/glean-gene)[5]. All Glean-predicted genes were retained, as were all genes supported by RNA-seq data and those predicted using two or more *de novo* methods (that is, Augustus, GlimmerHMM and/or SNAP). The open reading frame of each gene was predicted using BestORF (www.softberry.com). To assess the quality and accuracy of the predicted gene set, we examined the length-distribution of all genes, coding sequences, exons and introns, and the distribution of exon numbers for individual genes, and then compared these parameters with those calculated for the published gene sets of *B. malayi*, *C. elegans*, *P. pristionchus* and *M. incognita* (Supplementary Fig. 4).

Following prediction of the finalized gene set, we conducted pairwise analysis of the overall synteny existing between/among the large (>1 Mb) assembly scaffolds for *B. malayi* and *A. suum* relative to the complete *C. elegans* chromosomes. This analysis was undertaken by conducting pairwise alignments among all *A. suum* or *B. malayi* (WS220 assembly: ftp://ftp.sanger.ac.uk/pub2/wormbase/releases/WS220/genomes/b_malayi/) scaffolds larger than 1 Mb in size and the *C. elegans* chromosomes using LASTz (http://www.bx.psu.edu/miller_lab/dist/README.lastz-1.02.00/README.lastz-1.02.00a.html), which were then joined using CHAINNET[49] and output as a .axt alignment from which large-syntenic regions were defined. The resulting alignment files were used to construct synteny images on scaleable vector graphics format using customized perl scripts (ZX). In addition, gene-level synteny analyses were conducted for one-to-one orthologous genes colocalizing to large *A. suum* or *B. malayi* assembly scaffolds (>1 Mb) according to ref. 9. Orthology was determined by pairwise reciprocal BLASTx comparisons between *A. suum*, *B. malayi* and *C. elegans* according to ref. 11. One-to-one orthologous genes shared between either *A. suum* or *B. malayi* and *C. elegans* but not shared among *A. suum* and *B. malayi* based on reciprocal BLASTp analysis were further confirmed by Hidden Markov Modelling using the *jackhmmr* command in the program HMMER 3.0 (ref. 50) and a highly permissive threshold (HMM cutoff: 10^{-2}).

We assessed the genome-wide variation in the exonic regions by mapping all raw reads from our transcriptomic data to the genomic coding domains using Maq[51], and calling SNPs with a minimum coverage threshold of ten reads. All mapped reads were assessed as synonymous (non-coding change), non-synonymous (coding change) or ambiguous (a SNP that was represented in our data set as an ambiguous IUPAC code wherein one nucleotide change would cause a synonymous mutation and the other a non-synonymous mutation) using a custom Perl script (snp_analysis.pl). All genes were then ranked based on their accumulation of SNPs to assess and identify their levels of conservation/variation relative to their

©2011 Macmillan Publishers Limited. All rights reserved

function. We reasoned that, in addition to the real effects of the variability of each gene on their accumulation of SNPs, these data would be influenced also by the coverage achieved for each gene, which is affected by the number of reads available for each gene (that is, their relative levels of transcription) and the length of each gene. Thus, before ranking, the SNP data for each gene was normalized for its calculated reads per kilobase per million reads (RPKM) and total gene length using the simple equation: SNPs per read per kilobase = total SNPs divided by RPKM divided by gene length (in bp) multiplied by 1,000 bp. Following ranking, we explored function among the 2.5% most variable (with the highest rankings based on normalized SNP data) and most conserved genes (with the lowest rankings based on normalized SNP data). Noting the potential inaccuracy associated with estimating the normalized SNP rankings of lowly transcribed genes (owing to a lack of data/coverage), only genes for which at least 100 reads were available were considered in these functional comparisons.

Functional annotation of coding genes. Following the prediction of the protein-coding gene set, each inferred amino acid sequence was assessed for conserved protein domains in the SProt, Pfam, PRINTS, PROSITE, ProDom and SMART databases using InterProScan[52], employing default settings. Gene ontology categories[53] were assigned to each contig inferred to contain at least one conserved protein domain. Gene ontology categories were summarized and standardized to level 2 and level 3 terms, defined using the GOslim hierarchy[54] using WEGO[55]. To characterize further the contigs/transcripts from *A. suum*, we conducted a series of high-stringency BLASTp homology searches (*e*-value cut-off: 10^{-5}) against a variety of databases. Each contig was assessed for a known functional orthologue, defined using the Kyoto Encyclopaedia of Genes and Genomes (KEGG) (www.kegg.com). Where appropriate, orthologous matches were mapped visually to a defined pathway using the KEGG pathway tool (available via www.kegg.com) or clustered to a known protein family using the KEGG-BRITE hierarchy tool (available via www.kegg.com). In addition, the amino acid sequence inferred from each *A. suum* coding gene was compared by BLASTp with protein sequences available for key nematode species (*B. malayi*, *C. elegans*, *P. pacificus* and *M. incognita*) as well as for *Drosophila melanogaster*[4] and *Mus musculus*[56] and those contained within the UniProt[57], SwissProt and TREMBL databases[58]. Key protein groups (for example, peptidases, kinases, phosphatases, GTPases, GPCRs, and transport and channel proteins) were characterized by high-stringency BLASTp homology searching (*e*-value cut-off $<10^{-5}$) of manually curated information sequence data available in the MEROPS[59], WormBase, KS-Sarfari (https://www.ebi.ac.uk/chembl/sarfari/kinasesarfari) and GPCR-Sarfari (https://www.ebi.ac.uk/chembl/sarfari/gpcrsarfari) and the Transporter Classification database[60]. E/S proteins were predicted using Phobius[61], employing both the neural network and hidden Markov models, and by BLASTp homology-searching of the validated signal peptide database[62] and an E/S database containing published proteomic data for *B. malayi*[63,64], *Schistosoma mansoni*[65] and *M. incognita*[66]. In the final annotation, proteins inferred from genes were classified based on a homology match (*e*-value cut-off: $\leq 10^{-5}$) to: (1) a curated, specialist protein database, followed by (2) the KEGG database, followed by (3) the UniProt/SwissProt/TREMBL databases, followed by (4) the annotated gene set for a model organism, including *C. elegans*, *D. melanogaster*, *M. musculus* or *S. cerevisiae*, followed by (5) the gene ontology classification, and, finally, (6) a recognized, conserved protein domain based on InterProScan analysis. Any inferred proteins lacking a match (BLASTp cut-off $\leq 10^{-5}$) in at least one of these analyses were designated hypothetical proteins. The final annotated protein-coding gene set for *A. suum* is available for download at WormBase (in nucleotide and amino acid formats).

Differential transcription analysis. Following RNA-seq, all paired-end reads for each library constructed were aligned to the predicted *A. suum* gene set using TopHat, and quantitative levels of transcription (RPKM)[67] were calculated using Cufflinks. Differential transcription was assessed[68] using a *P*-value cut-off of ≤ 0.01 and a minimum, two-fold difference in absolute RPKM values. False discovery rates for differential transcription were determined[68]. To allow the rapid visual assessment of the statistically significant changes in transcription of each gene between and among individual libraries, we constructed heat-maps representing absolute differences in the RPKM values, calculated for each transcript using a customized Perl script (express_heatmap_RPKM.pl). Genetic interaction networks were predicted[69] based on data available for homologous genes in *C. elegans* (inferred from BLASTp comparisons) and viewed using the program BioLayout 3D[70].

Essentiality and druggability predictions. *A. suum* genes with homology to those in the *C. elegans* and/or *D. melanogaster* genomes were inferred based on BLASTp comparisons using the predicted protein sequences for individual species (*e*-value cut-off 10^{-5}). Phenotypic data for each *C. elegans* and *D. melanogaster* homologue were sourced from WormBase and FlyBase (www.flybase.org), respectively. *A. suum* genes determined[71] to have homologues with lethal phenotypes in both *C. elegans* and *D. melanogaster* were inferred to represent essential genes. Metabolic chokepoints were defined[29,72] and assessed based on *A. suum* gene sequences determined, by BLASTp comparison (10^{-5}), to have an orthologue in the KEGG database. All 'essential' homologues and/or molecules in 'chokepoints' were then queried against the BRENDA[73] and CHEMBL databases (accessible via https://www.ebi.ac.uk/chembldb/), to identify known chemical inhibitors.

Additional bioinformatic analyses, and use of software. Data analysis was conducted in a Unix environment or Microsoft Excel 2007 using standard commands. Bioinformatic scripts required to facilitate data analysis were designed using Perl, BioPerl, Java and Python and are available via http://research.vet.unimelb.edu.au/gasserlab/.

Androgenetic alopecia • Hair loss • Mediterranean Diet • Nutrition

Summary

Hair loss is a widespread concern in dermatology clinics, affecting both men's and women's quality of life. Hair loss can have many different causes, which are critical to identify in order to provide appropriate treatment. Hair loss can happen due to many variables, such as genetic factors or predisposition, vitamin and mineral deficiencies, skin problems, hair growth disorders, poor diet, hormonal problems, certain internal diseases, drug use, stress and depression, cosmetic factors, childbirth, and the chemotherapy process. Treatment for hair loss varies depending on the type of alopecia, deficiency, or excess of structures such as vitamins and minerals, and also on hair and skin structure.

The Mediterranean diet is characterized by low amounts of saturated fat, animal protein, and high amounts of unsaturated fat, fiber, polyphenols, and antioxidants. The main nutrients found in the Mediterranean Diet are rich in antioxidant, anti-inflammatory components. It also has an important place in hair loss treatment, since recently treatment strategies have included polyphenols and unsaturated oils more and more frequently. The goal of this work was to review published articles examining alopecia and its types, the many micronutrients that affect alopecia, and the role of the Mediterranean diet in alopecia. The literature shows that little is known about hair loss, nutritional factors, and diet, and that the data collected are conflicting. Given these differences, research into the function of diet and nutrition in the treatment of baldness is a dynamic and growing topic.

Introduction

Hair loss or alopecia, a clinical condition that is frequently seen in dermatology clinics, can be caused by many etiological factors and it significantly affects the patients' quality of life [1]. This group of diseases is basically divided in two subgroups: cicatricial alopecias and non-cicatricial alopecias. While cicatricial alopecia may progress with loss of follicles, thus causing irreversible hair loss, this condition is usually reversible in non-cicatricial ones. Many causes are known to have a role in non-cicatricial alopecia, including emotional issues, chronic disorders, dietary inadequacies, trace elements, and vitamin deficiencies [2]. Other factors can be stress, drug use, immune system, endocrine disorders, and genetic and epigenetic changes [3].

A balanced and regular diet is very important for healthy hair: sudden weight loss, low-caloric diets, unbalanced diet, obesity, and excessive intake of vitamin and mineral supplements can cause hair loss. Micronutrients, which are the main elements of the hair follicle cycle, are very important in alopecia, which is why dietary supplements (mostly vitamin and mineral) are among the preferred methods to prevent hair loss. Given the frequency of hair loss in current times and its impact on the patients' social lives, finding effective alopecia treatments impacts a huge portion of the population [2].

The role of diet in the development and treatment of alopecia has recently been a hot topic of research. It has been found that plant-rich diets – such as the Mediterranean Diet (MD), whose main nutrients are rich in antioxidants, anti-inflammatory, and estrogenic components – include chemicals that stimulate hair growth and reduce hair loss. These diets contain phytochemicals that promote hair development by lowering the generation of reactive oxygen species in the dermal papilla cells, causing growth hormones to be secreted [4].

This is why dietary practices characterized by a large intake of anti-inflammatory, antioxidant and estrogenic activities are emphasized as additional treatments for alopecia. This review aims to explain the general background of alopecia, to emphasize the role of nutritional and dietary supplements in the treatment of alopecia, and to consider the effects of herbal treatment methods on alopecia patients.

Alopecia and types of alopecia

Alopecia is the partial or complete loss of hair, which can be caused by a disruption in the hair development

https://doi.org/10.15167/2421-4248/jpmh2022.63.2S3.2765

cycle or by damage to the hair follicles as a result of systemic or local factors such as genetics, hormone imbalances, and infection [5-7].

The hair growth cycle consists of four stages: the anagen phase (the growth phase, which is also the longest, lasting 2-7 years); the catagen phase (the transitional phase, lasting up to 2 weeks, which includes hair follicle involution due to apoptosis); the telogen phase (the resting phase, lasting up to 12 weeks); and the exogenous phase (the release phase of telogen hair) [8].

The fact that alopecia is affected by many factors causes the existence of a wide number of types of alopecia. Androgenic alopecia, alopecia areata, chemotherapy-induced alopecia, anagen effluvium, telogen effluvium, traction alopecia, and trichotillomania are some of the most common kinds. The clinical classification system of Rook and Dawber divides all types of alopecia into two categories: cicatricial alopecia and non-cicatricial alopecia [6, 7].

CICATRICIAL ALOPECIAS

Cicatricial alopecias (CAs) are clinical pathological conditions that describe permanent hair loss caused by the replacement of damaged hair follicles with fibrotic scar tissue. They are classified into two groups, primary cicatricial alopecia (PCA) and secondary cicatricial alopecia (SCA) [9, 10].

The PCA group includes multiple inflammatory diseases with distinct clinical and histopathological features and unknown and irreversible causes, primarily affecting and destroying hair follicles. It is responsible for 7% of all hair loss cases. PCA is subdivided into lymphocytic, neutrophilic, or mixed subtypes [11, 12]. Chronic cutaneous lupus erythematosus, lichen planopilaris, classic Brocq pseudopelade, folliculitis decalvans, and dissection folliculitis are some of the diseases with clinical conditions [13].

The SCA group includes inflammatory and neoplastic conditions and physical traumas that usually affect primarily the dermis and cause secondary follicular destruction [9]. While in PCAs the disease directly affects hair follicles, in SCAs they disappear due to secondary reasons. Factors affecting SCA formation include genodermatoses, permanent alopecia due to developmental defects, physical and chemical injuries, infections, inflammatory dermatoses, drug uses, and neoplastic conditions [14]. The classification of cicatricial alopecias is summarized in Table I.

NON-CICATRICIAL ALOPECIAS

Non-cicatricial alopecia is reversible alopecia, characterized by an altered hair cycle and by the fact that hair follicles are preserved [5].

Non-cicatricial alopecias are divided in local alopecias and diffuse alopecias [17]. Local alopecias include alopecia areata, tinea capitis, and trichotillomania. Diffuse alopecias include alopecia totalis or universalis, telogen or anagen effluvium. The classification of non-cicatricial alopecias is summarized in Table II. The most common alopecia in this group is androgenic alopecia.

Androgenic alopecia, caused by the miniaturization of hair follicles, is the most common type of progressive hair loss, affecting 30-50% of men and approximately 30% of middle-aged women. Alopecia areata, the second most common type of non-cicatricial alopecia, is known to be associated with autoimmune problems [5].

Common causes of hair loss

As previously stated, the hair growth cycle consists of four phases: anagen, catagen, telogen, and exogen. Hair loss differs according to the affected stage. Although there are many different reasons for hair loss, androgen and stress-related causes are usually underlying. Other systemic causes of hair loss include telogen effluvium, nutrition, endocrine imbalances, drugs, infections, special diseases, malignancies, problems with the immune system, environmental factors, age, and genetic factors [3].

ANDROGEN-RELATED ALOPECIA

The most common type of hair loss is androgenetic alopecia, which affects 80% of men and 50% of women. In this kind of alopecia, genetic factors and age-related causes affect the androgen mechanism, which is the one allowing vellus hair to turn into longer, thicker, and darker terminal hair: the defect in this mechanism makes it function differently by stimulating the regression of hair follicles to turn into vellus hairs. Androgenetic alopecia is a dynamic and continuous hair loss problem, in which mast cells and lymphocytes are defined around the miniaturized follicle, rich in stem cells [18-20].

Although androgens play an important role in androgenetic alopecia, genetic predisposition is also important: genetic background plays an important role, with a rate of 0.81 in twin studies, thus showing familial clustering. Having a polygenic feature, its genetic background is complex. However, changes in the androgen receptor (AR) gene and 5-alpha reductase gene were found to be effective in androgenetic alopecia. In addition, triple repeat polymorphisms have been associated with single nucleotide polymorphisms. It has been stated that the AR gene on the X chromosome and the ectodysplasin A2 receptor (EDAR2) gene are related and that polymorphisms in this gene are associated with androgenic alopecia, but its exact role has not been fully defined. Androgenetic alopecia is associated with genetic alterations in the WNT signaling pathway, which regulates dermal papilla cells and androgen metabolism. Expression studies and epigenetic studies are limited, as scalp biopsy is difficult to obtain. Overexpression of prostaglandin synthase (PGDS) and the PGDS product prostaglandin D2 (PGD2) restrict hair development by generating an early catagen phase, according to the limited study [8, 21].

STRESS-INDUCED ALOPECIA

Stress is one of the most common reasons of hair growth disorders and hair loss, since it leads to an increase in the level of cortisol released into the body. It has been proven

Tab. I. Classification of cicatricial alopecias [9, 14-16].

Primary Cicatricial Alopecia (working classification of PCA by North American Hair Research Society)	Secondary Cicatricial Alopecia		
Lymphocytic	Chronic cutaneous lupus erythematosus, Lichen planopilaris, Frontal fibrosing alopecia, Graham Little syndrome, Classic pseudopelade (Brocq), Central centrifugal cicatricial alopecia, Alopecia mucinosa, Keratosis follicularis spinulosa decalvans	Physical or chemical trauma	Burns, Toxic/corrosive substances (e.g. acid or alkali burns), Ischemia/pressure, Traction/ trichotillomania (end stage)
		Ionizing radiation	Radiation
		Infections	Bacterial infections, Viral infections, Fungal infections (tinea capitis, in particular, deep trichophytosis caused by zoophilic pathogens)
Neutrophilic	Folliculitis decalvans, Dissecting cellulitis/folliculitis	Malignant and benign tumors	Primary tumors, Metastases, Lymphoproliferative diseases, Epidermal and organoid nevi
		Genodermatoses	Aplasia cutis congenita, Ectodermal dysplasia, Ichthyosis, Epidermolysis bullosa, Darier's disease, Incontinentia pigmenti, Hyalinosis cutis et mucosae
		Granulomatous diseases	Sarcoidosis, Necrobiosis lipoidica
Mixed	Folliculitis (acne) keloidalis, Folliculitis (acne) necrotica, Erosive pustular dermatosis	Autoimmune diseases	Graft–versus–host disease, Scleroderma (en coup de sabre), Lichen sclerosus, Blistering dermatoses (cicatricial pemphigoid)
Non-Specific	Idiopathic scarring alopecia with inconclusive clinical and histopathological findings, End stage of various inflammatory scarring alopecias	"Deposition" dermatoses	Amyloidosis, Mucinosis
		Inflammatory diseases	Psoriasis, Pityriasis amiantacea

that cortisol has a negative effect on the formation mechanism of the hair follicle by breaking down hyaluronan and proteoglycans, which are integrating substances in the extracellular matrix and skin. Acute and chronic stress is known as the main cause of telogen effluvium. Stress also can aggravate the types of alopecia that are primarily caused by endocrine imbalances, immunological responses, and toxic causes. In addition, the stress that occurs in response to hair loss causes hair loss to continue. In animal studies, chronic stress has been associated with hair growth arrest, increased granulation of mast cells, and perifollicular inflammation. Further studies have also shown that certain stress mediators, such as substance P, adrenocorticotropic hormone, prolactin, and cortisol, inhibit hair growth [22].

TELOGEN EFFLUVIUM

Telogen effluvium is a scarless hair loss condition caused by physiological stress (such as delivery, rapid weight loss, mental stress, long-term drug usage), medical conditions like hypo/hyperthyroidism, post-diet effects, and prolonged fasting. Although it is generally reversible, it affects the psychosocial status of the patients, and its mechanism has not been discovered yet. Telogen effluvium is difficult to diagnose and treat because there are many factors at play in the etiology of the disease [23, 24].

ENDOCRINE IMBALANCES

The formation of hair follicles occurs as a result of a molecular genetic process regulated before birth. Many hormones and their receptors play important roles in the healthy progression of this process: thyroid hormones, glucocorticoids, insulin-like growth factor-I, and prolactin are all hormones that influence hair development, although androgens are the most important ones. In addition, vitamin D receptors and retinoid X receptors are also effective in postpartum hair growth [21, 25].

IMMUNE SYSTEM

Alopecia areata and primary cicatricial alopecia are two common forms of immune-mediated alopecia. Alopecia areata is a T-cell-mediated autoimmune illness that affects hair follicles in the anagen stage. The JAK-STAT (Janus kinase-signal converter and transcription activator) signaling pathway is involved in its development [26].

The concept of immune privilege is the phenomenon of protection of organs or tissues that can be seen in the corneal tissue, testis, placenta, liver, intestine, brain, hair follicle, and mucosal tissues from autoimmune threats developed by the host's immune system [27].

Hair follicles in the anagen stage are protected from unwanted immune responses by exhibiting immune privilege from the protrusion level to the bulb. The key mechanisms are the lack or reduction of MHC class I and MHC class II expression, signaling that there is no risk with the CD200 signal, and the absence of antigen presentation. In the development of alopecia areata, collapse is observed in the anagen hair bulb. While NKG2D+ T cells and natural killer (NK) cells rapidly increase in the medium, perifollicular mast cells exhibit proinflammatory properties and interact with CD8+ T cells that recognize autoantigens [26-28].

The intense presence of CD8+CD3+ cytotoxic T cells in anagen stage hair follicles and the more targeting of pigmented hair suggest that the targets of cytotoxic T cells are melanocytes and melanogenesis-related autoantigens. The fact that over 100 single nucleotide polymorphisms are associated in studies indicates the importance of the genetic background [26, 28].

Studies have shown that in primary cicatricial alopecia there is a loss of immune privilege in the protrusion region. Although it is not exactly known what causes the loss of immune privilege, it is thought that among the causes might be perifollicular/intrafollicular increase in skin microtrauma, infectious or psycho-emotional stressors, bacterial superantigens, mast cell degranulation, and ectopic interferon γ (IFN-γ) secretion [26].

OTHER CAUSES OF ALOPECIA

Drug-induced alopecia is a type of non-scarring alopecia involving the scalp, which occurs when one of the two main mechanisms of the normal hair growth cycle, anagen effluvium or telogen effluvium, is stopped. When the drug is stopped, the hair loss improves. Other body hairs are rarely affected by drugs [29]. Anti-hypertensives, anti-arrhythmics, statins, anti-metabolites, psychotropic agents, anti-convulsants, anti-coagulants, antiretrovirals, and H2 blockers are among the drugs that cause hair loss [3].

Hair loss is also known to be caused by agents such as bacterial infection Treponema pallidum, viral infection Epstein-Barr virus, HIV, hepatitis C, varicella-zoster virus, and cytomegalovirus [3].

Hair loss and subsequent alopecia are seen as a result of diseases such as liver and kidney failure, rheumatological disorders, discoid lupus erythematosus, connective tissue disorders, amyloidosis, cutaneous sarcoidosis, systemic sarcoidosis [3]. Alopecia can also be seen in systemic and cutaneous hematological malignancies. Although it is usually associated with mycosis fungoides, hair loss is common in cutaneous T-Cell lymphoma [3, 30].

Nutrition and hair loss

The integrity of the normal function of healthy skin and hair depends largely on an adequate and balanced diet. Whether a nutritional imbalance is a general or specific deficiency, an excessiveness of one component over another can compromise the organism's balance. When looking at the studies published in the literature, it is apparent that the nutritional elements that cause hair loss in healthy adults are still to be thoroughly determined.

In the first published reports in this domain, that are animal studies carried out in the first half of the XX century to explain the relationship between nutritional factors and hair loss, Cunningham identified iron deficiency in rats in 1932, Sullivan and Nicholls found riboflavin deficiency in 1941, and Day studies reported that zinc deficiency causes hair loss in both rats and mice [31-35]. The discovery and identification of vitamins related to dietary deficits have had a profound impact on the evolution of nutrient medicine since the first clinical trials. People frequently look for information on vitamin and mineral supplements and diets to prevent or treat many skin disorders, including hair loss. Hair loss greatly affects a person's appearance and personality in physical and social aspects. As a result, hair loss has a negative impact on the standard of living of men and women alike, therefore making the treatment of alopecia essential [36, 37]. Among the about 100,000 hair follicles on the human scalp, 90% of them are in the anagen phase without alopecia, requiring critical nutrients including proteins, vitamins, and minerals to create healthy hair [38]. As a result, trace elements, such as vitamins, are crucial dietary components [39]. Vitamins and trace elements are micronutrients that are critical elements of the diet, even though they are only required in minute amounts. The normal cycle of hair follicles is dependent on micronutrients as they play a role in cell renewal, which is common in rapidly dividing hair follicles [40]. Furthermore, several micronutrients are suggested to minimize oxidative stress because they play a role in alopecia pathogenesis [41]. As a result, a detailed understanding of the significance of these micronutrients could aid research into alopecia prevention and therapy [40].

MICRONUTRIENTS

Vitamin A, which is made up of a set of unsaturated chemical compounds such as retinol, retinal, and retinoic acid, is an essential nutrient that humans cannot generate and thus it must be taken from diet [42]. Vitamin A and its compounds are required for a variety of functions throughout life, including immune function, cell differentiation and proliferation, reproduction, growth, maintenance of epithelial cell integrity, vision, and embryogenesis [43, 44]. Generally, excessive vitamin A consumption can lead to hair loss in most people [45].

In one study, dietary vitamin A activates follicle stem cells by activating the hair cycle developmental and growth phases in a dose-dependent manner (anagen) [46, 47]. For healthy hair, it is important to maintain homeostasis and, accordingly, to maintain an appropriate concentration of the active metabolite [48]. A sufficient level of vitamin A may usually be obtained via a well-balanced diet. One case reported of a 60-year-old man who took too much vitamin A and had non-scarring fronto-central alopecia and a decrease in pubic and axillary hair. These changes were accompanied by drug toxicity associated with excessive intake of vitamin A by the patient [49]. In conclusion, these studies show that there are some optimal levels of vitamin A that are suitable, but very little or too much of this molecule contributes to the formation, maintenance, or advancement of alopecia [40].

The only vitamin B produced by the body is B7 (biotin). The recommended daily amounts of the vitamin B complex, which are pantothenic acid, riboflavin, thiamine, niacin, B6, B12, and folate, can be taken through a balanced diet. Lack of biotin is extremely uncommon in people who eat a healthy, well-balanced diet, and biotin supplements are not necessary [50]. Hair loss has only been linked to B2 (riboflavin), B7 (biotin), B12, and folate deficits. Biotin (vitamin H or B7) is a vitamin B complex with five carboxylases (acetyl-CoA carboxylase, 3-methylcrotonyl-CoA carboxylase, pyruvate carboxylase, and propionyl-CoA carboxylase) [50]. In addition, biotin is effective in cell signaling, histone modifications, and gene regulation [51]. Biotin lack is a condition that can be inherited or acquired; the inheritance pattern is autosomal recessive and there can be neonatal and infantile forms. It is caused by a lack of the enzyme holocarboxylase synthetase and appears from the first six weeks of life; it can be a potentially fatal disease in newborns. Diffuse dermatitis and alopecia are common among survivors. The scalp may be devoid of vellus and terminal follicles, and may also lack lanugo hairs, eyebrows, and eyelashes. Hair on the scalp, eyebrows, and eyelashes may be present but sparse or completely lost [52, 53].

Despite the popularity of biotin, there is still insufficient evidence in randomized controlled trials to support that supplementing this micronutrient prevents or treats hair loss. There are no clinical studies showing that biotin supplements are effective in treating hair loss unless people are deficient [54]. Hair loss, rashes on the skin, and fragile nails are all signs of biotin deficiency. In one study, 38% of women suffering from hair loss had low levels of biotin [55].

Humans cannot produce folate. Folate is essential for cell division and maintenance, and for synthesis of the nucleotide (thymidine), which is required for DNA repair. Folate also plays an important role in the 'site-specific' methylation of the cytosine base in gene expression. Remethylation of plasma homocysteine to methionine is another action of folate/folic acid. This water-soluble vitamin's demand is satisfied in part by dietary folate and in part with the use of synthetic folic acid [56]. Hair, skin, and nail changes may indicate a lack of folate [38]. Vitamin B12 (also known as cobalamin) is needed to activate folate, which is essential for DNA synthesis. Inadequate nutrition causes impaired nerve transmission and insufficient erythrocyte and other hematological cell production. B12 is an essential nutrient in the transfer of a methyl group in a reaction that requires methionine synthase, which converts homocysteine to methionine. This reaction activates folate, which can be used in DNA synthesis. Myelin production, and thus the preservation and repair of nerve axons, both require B12. In addition, B12 is required for energy synthesis in mitochondria and erythropoiesis in the bone marrow [57].

Due to the effect of B12 and folate on nucleic acid, it has been highlighted that they could play a role in the proliferation of hair follicles [38]. Additionally, a case-control review of dietary research on alopecia areata found no changes in vitamin B12 values in patients with and without alopecia areata. Although vitamin B12 appears to not affect hair growth and repair, research on the subject is scarce [53].

Ascorbic acid, often known as vitamin C, is a water-soluble vitamin produced as a product of glucose metabolism. Vitamin C has a chelating and reducing effect. This effect helps intestinal absorption and mobilization of iron [58, 59]. Accordingly, vitamin C supplementation is critical for patients suffering from hair loss due to iron deficiency [38]. The enzyme l-gulonolactone oxidase, which is necessary for the production of vitamin C, is evolutionarily deficient in humans, which is why vitamin C must be received from diet [60]. The pathophysiological role of vitamin C in the hair cycle is poorly known [53]. Citrus juices contain large amounts of vitamin C, and patients with iron deficiency are recommended to take oral supplements such as orange juice [61]. While vitamin C insufficiency has been linked to anomalies in body hair [59], there's still no evidence of a link between vitamin C values and hair loss.

Vitamin D is a steroid hormone that is fat-soluble. Vitamin D plays a regulatory role in various pathways, such as calcium absorption, bone mineralization, immune system, and DNA transcription [62, 63]. Vitamin D, whether obtained from diet or through the skin, is inactive and must be activated by enzymes [38]. Vitamin D insufficiency is a typical occurrence [64]. It was observed that vitamin D has an effect on the hair cycle in animal research. By attaching to the nuclear vitamin D receptor (VDR), vitamin D regulates keratinocyte development and differentiation. VDR immunoreactivity

Tab. II. Classification of Non-Cicatricial Alopecias [17].

Diffuse Alopecia	Local Alopecia
Female pattern hair loss	Alopecia areata
Male pattern hair loss	Tinea capitis
Diffuse alopecia areata	Traction alopecia
Alopecia totalis or universalis	Trichotillomania
Telogen effluvium	
Anagen effluvium	

is highest in the anagen phase in murine hair follicle keratinocytes [38, 53]. Vitamin D thus plays a function in alopecia and may be the cause of hair loss in vitamin D-deficient rickets patients [65]. Alopecia, hypocalcemia, rickets, hyperparathyroidism, and osteomalacia develop in mice lacking the vitamin D receptor (VDR). Normalizing mineral ion homeostasis prevents all these abnormalities, except alopecia. Hair regeneration experiments in athymic nude mice demonstrate that the lack of VDR in keratinocytes results in a defect in anagen initiation, similar to the one observed in mice without VDR. Although these studies show that expression of the VDR in keratinocytes is necessary, they do not prove that it is sufficient to maintain the normal hair cycle [66]. Patients with VDR mutations who develop vitamin D resistance also suffer from severe alopecia of the body and scalp [53, 65]. In two patients with inherited vitamin D-resistant rickets and baldness, Forghani et al. discovered novel nonsense mutations in the VDR gene [67, 68]. Daroach et al. compared patients with alopecia areata to healthy controls in a prospective study to correlate VDR expression in alopecia areata patients, finding higher vitamin D deficiency levels in the alopecia group [69]. To better understand the effects of vitamin D in alopecia, more large-scale research is required [68].

Iron is vital for all cellular functions because of its role in electron transport, oxygen delivery, and enzyme activity. It includes a wide range of enzymes, from hydroxylases – regulating cellular metabolism – to demethylases – changing DNA chromatin and consequently gene expression [70]. Iron is vital in rapidly proliferating cells, such as those in the hair follicle matrix, since it is a cofactor for ribonucleotide reductase, the rate-limiting enzyme in DNA synthesis. Some studies have demonstrated that various genes in the hair follicle are regulated by iron [71]. Iron deficiency, which also causes telogen effluvium, is the most frequent dietary deficiency worldwide [72, 73]. The level of serum ferritin, also known as iron-binding protein, is an important correlate of total body iron stores and is utilized in hair loss research as an indicator. Iron deficiency is frequent in women who are experiencing hair loss [31]. A mutation in the *TMPRSS6* gene caused the "mask mouse" to lose body hair and develop iron deficiency anemia, according to a study conducted by Du et al. A mutation in *TMPRSS6* was linked to an inability to downregulate *HAMP* expression in mice, and elevated hepcidin levels were linked to reduced dietary iron absorption and, as a result, iron insufficiency. Iron treatment, interestingly, corrected iron deficiency and stimulated hair growth in these animals [74]. Further research is needed to develop iron supplementation guidelines, therapy markers, and cures for patients suffering from hair loss due to iron deficiency.

Selenium (Se) is primarily involved in thyroid hormone metabolism, redox homeostasis, and enzymatic activity like glutathione peroxidases (GPx) as an important microelement. The antioxidant potential of other selenoproteins is thought to have a significant impact on human health [75]. Hair loss has been observed in selenium-deficient rats [76] and in knock-out mice lacking a selenium cofactor protein [77]. Although these findings suggest a link between selenium deficiency and hair loss, the role of selenium in human hair follicles is still not fully understood. Hair loss can be caused by selenium toxicity [53]. Among people who have been diagnosed with selenium toxicity, 72 percent was affected by hair loss affected, losing 10 percent to 100 percent of their hair [78]. After starting daily selenium therapy in 6 infants with pseudoalbinism alopecia-like findings, alopecia and pseudoalbinism improved when serum selenium levels reverted to normal [79]. Another clinical study showed that there was a significant reduction in hair loss and other gastrointestinal symptoms in ovarian cancer patients who received selenium supplements during chemotherapy as compared to controls. This result shows that selenium has a beneficial effect during chemotherapy [80]. Selenium is thought to play a role in the hair cycle, and healthy people can obtain enough through their diet. Supplementation is not suggested unless there are known deficits, particularly given the risk of hair loss due to toxicity.

Zinc is a trace element that is essential for a variety of cellular functions through proteins, enzymes, and zinc fingers, and also acts as a multitude of transcription factors important in gene regulation [81, 82]. Zinc deficiency can cause telogen effluvium, thin white and brittle hair, as well as many dermatological problems [83]. Superoxide dismutase is one of the zinc-dependent enzymes, which is thought to be one of the contributing factors to alopecia areata [84]. The function of antioxidant processes in alopecia areata is a popular issue in the scientific community. Zinc has also been linked to the Hedgehog signaling pathway, which has been linked to hair follicle morphogenesis [53]. Although zinc homeostasis impairment has been linked to a number of issues, its diabetic effects and function in metabolic syndrome are still being researched [85]. Zinc is a cofactor for enzymes involved in dopamine transport [86], cell membrane stabilization [87], and prostaglandin metabolism. Data relating zinc levels to telogen effluvium and androgenetic alopecia are not homogeneous. In another study comparing 312 people with hair loss with 32 controls, patients with alopecia areata and telogen effluvium showed low zinc levels [88].

In summary, nutritional supplement can damage the hair, when taken without a cause: a surplus dosage of micronutrients, including vitamins A and E, as well as selenium, has been linked to hair loss [83]. Hypervitaminosis A can cause hair loss, and findings on the effects of isotretinoin on hair loss back up this theory. Even though the connection between vitamin D values and telogen effluvium or androgenetic alopecia is still contested, most researchers concur that patients having alopecia and vitamin D insufficiency should take vitamin D supplements. On the other hand, people with iron-deficient alopecia need vitamin C. There is no evidence that vitamin E has a function in androgenetic alopecia or telogen effluvium. Women with hair loss are more likely to be lacking iron. In individuals with iron insufficiency and/

or low ferritin, many researchers deem that iron supplementation is necessary. Data on zinc concentrations in telogen effluvium and androgenetic alopecia are not yet clear and zinc screening is not advisable. It can be also a cause of hair loss, selenium toxicity, and riboflavin deficiency. Nevertheless, there are still no comprehensive studies to make any recommendations about screening for riboflavin or selenium. Hair loss can be caused by a lack of biotin. However, there is no proof that biotin supplementation increases hair growth. Exogenous biotin may also interfere with several laboratory tests, resulting in erroneous negative or positive results. Although some research has been carried out on the link between hair loss and B12 or folate/folic acid, currently there is not enough data on these dietary supplements.

Mediterranean diet and hair loss treatment

The Mediterranean Diet (MD), among the healthiest nutrition models accepted by the whole world, was put forward by Prof. Ancel Keys and his friends from examining the typical diet in Southern Italy and Greece. The MD is characterized by a low intake of saturated fat and animal protein, by a high intake of unsaturated fats, fiber, and antioxidants, and by appropriate intake of omega-6/omega-3 fatty acids. It is generally rich in vegetables, fruits, legumes, nuts, grains, fish, and unsaturated fats, with small amounts of meat and dairy products [89-91]. In the Seven Country Study, the MD has been linked to a lower risk of coronary artery disease. In addition, several studies support its effectiveness in preventing diabetes, obesity, and even various types of cancer [89, 91]. This is thought to be related to an adequate intake of polyphenols, which play a critical role in the MD. Polyphenols have genomic effects that play a part in the inactivation and activation of regulatory genes. They also exert epigenetic effects by modulating the expression of microRNAs, regulating mechanisms such as DNA methylation and histone modification, and chromatin rearrangement [91, 92]. The genetic and epigenetic effects of polyphenols, one of the main components of the MD, on the genome have recently been the focus of attention for researchers.

In addition, polyphenols protect the body against harsh climatic conditions and oxidative stress, which are involved in the defense against ultraviolet radiation and pathogen attacks in plants. Diets rich in these secondary metabolites found in fruits, vegetables, fiber foods, cereals, and beverages protect against the development of chronic and neurodegenerative diseases, diabetes, cancer, cardiovascular diseases, aging, and hypertension in humans [93]. Polyphenols can act as antioxidants, stimulate cell signaling pathways, and reduce inflammation by blocking gene activity. Studies have proven that the MD plays an important role in reducing inflammation [94]. The presence of over 8,000 polyphenols identified so far and the differences between the regions of the MD are considered limiting factors in the study of the effects of this diet. However, the protective effect of polyphenols has been proven by many studies [91, 93]. Plants containing flavonoids are promising in terms of reducing hair loss or stimulating hair growth [95].

The effects of the main components of the foods consumed in the MD are examined in hair loss and in many other diseases. Studies have shown that the polyphenolic compounds in tea significantly increase hair growth. In addition, it has been reported that epigallocatechin-3-gallate, the main component of tea polyphenols, can reduce the risk of androgenetic alopecia by inhibiting 5α-reductase, which increases hair growth in humans [96].

Essential fatty acids (linolenic, linoleic, oleic, myristoleic, palmitoleic, and stearic acids) found in olive oil, which has an important place in the MD, have inhibitory effects on 5α-reductase (5AR) that provide hair regrowth [4, 18, 97]. It has been reported that hair loss and depigmentation are seen in hair and eyebrows in people affected by linoleic acid and alpha-linolenic acid deficiency [83]. Mice with testosterone-induced alopecia showed a significant increase in hair growth after day 16 of topical applications of hydroalcoholic extracts of rosemary, which is a polyphenol. In vitro tests showed strong inhibition of the 5AR enzyme binding to the dihydrotestosterone (DHT) receptor [98, 99]. Although not fully proven, topical applications of coconut oil for hair loss treatment continue to be used [100].

Polyunsaturated fatty acids are thought to be absorbed into mast cell membranes, altering membrane-associated enzymes such phospholipases, which affect mast cell exocytosis. In a monkey study, it was shown that supplementing polyunsaturated fatty acids reduced hair loss in slightly alopecic monkeys; however, the cause of the hair loss was unknown [101].

A plant nanoparticle of safflower oil body loaded with human fibroblast growth factor 10 (hFGF10) in mice with androgenetic alopecia was found to accelerate hair regeneration by targeting hair follicles and reducing inflammation without any toxicity It has also been found to reduce hair follicle inflammation by inhibiting the overproduction of TNF-α, IL-1β, and IL-6 in macrophages and increasing the proliferation of dermal papilla cells. In this respect, it can be seen as a viable treatment option in androgenetic alopecia [102]. The standardized para rubber seed oil has been proven to be a safe and efficient bio-oil to stimulate hair growth or reduce/suppress hair loss [103].

Although there are many products for the treatment of alopecia, their effectiveness is controversial; research thus focuses on more effective pharmaceutical product development. As a result, the bioactivity of oligomeric procyanidin, a dimeric derivative from apples that can stimulate hair epithelial cell proliferation and induce anagen phase in vitro and in humans, is a popular application [104].

In one study, it was observed that resveratrol, an antioxidant, anti-inflammatory, and anti-apoptotic agent, when applied to mice, stimulated the transition of the hair cycle from the telogen phase to the anagen phase, delayed the transition to the catagen phase, and protected the hair follicle from oxidative damage. Resveratrol is considered to be a potential candidate drug for the treatment of alopecia [105]. In addition, a topical lotion containing Redensyl and Sepicontrol A5 polyphenols is used as an alternative treatment for androgenetic alopecia, as it is very safe and provides patient satisfaction [106]. When given to rabbits, *Ficus benghalensis* leaf extracts were found to be effective in increasing hair follicle development by lowering the action of 5-reductase II [107].

As a result, a lack of certain nutrients, such as vitamins, minerals, vital fatty acids, and proteins, can cause hair loss, structural anomalies, and color changes, albeit the exact causes remain unknown [83]. Hair loss is prevalently treated by dermatologists, and it has a significant psychological and emotional impact on patients. Micronutrients like vitamins and minerals have a vital, though not completely understood, role in hair follicle formation and in immune cell activity. A lack of these micronutrients could be a modifiable risk factor for the development, prevention, and treatment of alopecia.

It has been proven by studies that those who follow the MD have less risk of alopecia. As the use of polyphenol-based phytochemicals – frequently used in the MD– increases, the effect of polyphenols in the treatment of alopecia is taken into consideration. In addition, in several studies essential oils were used in the treatment of alopecia, leading to positive results [4, 91].

Considering all the data, more research is needed soon on the role of nutrients in the hair cycle, its association with known alopecia diseases, and effective supplementation regimens. The fact that the incidence of alopecia is low in those fed the MD is promising for the development of the most appropriate preventive and supportive treatments by further researching the active ingredients frequently used in the MD.

Keywords: efficacy, Hecolin, Hepatitis E virus, HEV 239, vaccine

Hepatitis E virus (HEV) infection is one of the main causes of acute hepatitis worldwide. A recombinant hepatitis E vaccine, HEV 239, has been licensed in China for immunizing adults of 16 y old and above. The vaccine antigen contains pORF2 aa 368 - 606 of the HEV genotype 1 expressed in *E. coli*. The quality of the vaccine is controlled through a combination of biophysical, biochemical and immunochemical methods. The vaccine is well tolerated in adults. The efficacy of the HEV 239 vaccine against symptomatic and asymptomatic infection had been proven to be high during a Phase III clinical trial and long-term follow up. The safety and efficacy of HEV 239 vaccine in certain high-risk populations remains to be further investigated.

Introduction

Hepatitis E (HE) is caused by infection with the hepatitis E virus (HEV). The awareness of this disease has increased a lot in recent years.[1] HEV infection remains a serious threat to life and productivity in the developing world. In the developed countries, an increasing number of autochthonous HE cases have been reported, suggesting that this threat is not limited to developing regions. Patients with underlying liver disease and patients who are immunosuppressed or immunocompromised are at particular risk.[2]

HEV is a non-enveloped, single-stranded, positive-sense RNA virus. It is the only member of the genus *Hepevirus* in the family *Hepeviridae*.[3] Four genotypes of HEV are associated with human diseases: genotypes 1 and 2 infect only humans, while genotypes 3 and 4 infect many animal species in addition to humans.[3,4] All 4 genotypes are characterized as one serotype, making the development of a univalent hepatitis E vaccine reasonable. Two candidate hepatitis E vaccines have been evaluated in clinical trials. The first of these, rHEV,[5] was developed by GlaxoSmithKine (GSK, Rixensart, Belgium). The other, HEV 239 (trade name Hecolin®),[6-8] was developed by Innovax (Xiamen, China) (**Table 1**). HEV 239 was launched in China in 2012. In this review, we focus on the development of the HEV 239 vaccine.

Structural basis for the HEV 239 vaccine

The HEV genome consists of 3 open reading frames (ORFs). ORF2 encodes a single structural protein (pORF2) for the HEV capsid. Structurally, the HEV capsid is arranged as a $T = 3$ icosahedral lattice, which assembles with the coordination of the HEV RNA genome.[9] The approximately 110 amino acid residues (aa) of the N-terminal region are responsible for RNA binding, given the positively charged arginine-clustered region here. With truncations in the 111 N-terminal aa and the 53 C-terminal aa, the protein can self-assemble into a $T = 1$ icosahedral VLP via a baculovirus / insect cell expression system.[10] The VLP form of genotypes 3 and 4 can be crystallized to allow the structural determination at a resolution of 3.5 Å.[11,12] The analysis of these structures has revealed 3 functional domains of pORF2, including the S domain (aa 118–313), which contributes to the 5-fold interaction and the formation of the basal shell; the P1 domain (aa 314–453), which is important for the 3-fold interaction; and the P2 domain (aa 454–606), which is involved in the 2-fold interaction and is responsible for host interactions.[11,12] The P2 domain, also called the E2s domain, was further analyzed, and its high-resolution crystal structure was determined. The crystal structure showed that two E2s form a tight homodimer through the strong hydrophobic interaction maintained by side chains of residues Val503, Trp548, Thr552, Ala555, Tyr557, Tyr561, Val598 and Val600 of both subunits of the dimer.[13] There is a unique groove region located on the most protrusive moiety along the 2-fold axis. This groove region was verified to be involved in virus-host interactions using site-directed mutagenesis and the binding of neutralizing mAbs.[13] The structure of the E2s domain in a complex with neutralizing mAb 8C11 further pinpointed the neutralization sites at Asp496-Thr499, Val510-Leu514, and Asn573-Arg578. Mutation and cell-model assays identified Arg512 as the most crucial residue for 8C11 interaction with and neutralization of HEV.[14] It should be noted that the epitope recognized by 8C11 represents a major immune dominant epitope. As such, it is capable of blocking naturally acquired anti-HEV from binding with the E2 antigen.[15]

HEV 239 was designed as ORF2 aa368–606 fragment from a further N-terminal truncation of $T = 1$ VLP and was adapted to be expressed with a high efficiency in *E.coli*.[16] During the development of the HEV 239 vaccine, some historic constructs based on antigenicity and immunogenicity were produced, including E2s (aa459–606), E2(aa394-606), HEV239(aa368-606) and T=1 VLP (112-607). E2s forms a dimer with 8C11 binding activity (**Fig. 1**).

Table 1. Characteristics of the 2 existing hepatitis E vaccines that have been evaluated in clinical trials

	rHEV	HEV 239 (Hecolin®)
Manufacturer	GlaxoSmithKine, Belgium	Innovax, China
Origin	HEV genotype 1	HEV genotype 1
Expression system	Baculavirus	E. coli
Gene location	ORF2 aa 112–607	ORF2 aa 368–606
Antigen content	20 μg	30 μg
Adjuvant	Aluminum hydroxide	Aluminum hydroxide
Immunization schedule	0, 1, and 6 month	0, 1, and 6 month
Sample size of the efficacy trial	2 000	112 604
Participants enrolled	Mostly male (99.6%), aged from 18–62 (mean age 25.2)	Female and male, aged from 16–65 (mean age 44.1)
Efficacy against hepatitis E in the PPS cohort	96% (95% CI, 86–99)	100% (95% CI, 72–100)
Efficacy against hepatitis E in the ITT cohort	89% (95% CI, 77–94)	96% (95% CI, 66–99)
Development stage	Phase II clinical trial finished	Licensed in China
Advantages and disadvantages	Efficacy in women and in some special population remains to be determined	Efficacy in some special population remains to be determined

PPS: per-protocol set; ITT: intention to treat.

E2 (aa394–606) forms a hexamer with considerable antigenicity and marked immunogenicity in rhesus monkeys. The N-terminal 26 aa extension of E2, called HEV 239, self-assembles into shrunken version of the virus-like particles of the ~20 nm diameter. These particulate particles verified with plausible antigenicity and immunogenicity.[16, 17] Although HEV 239 (aa 368–606) protein is N-terminally shorter than T = 1 VLP (aa 112–606) in aa sequence, but they share the structural feature of outmost moiety of viral capsid (**Fig. 1**), which, E2s, or called P2 domain, is responsible for virus-host interaction and subsequently accounts for antigenicity and immunogenicity in vaccine design. Compared with the complex expression in insect cell, production in E.coli is easy to handle and scale-up. HEV 239 can self-assemble into particles in vitro. However, T = 1 VLP was only found forming particle in insect cell (rHEV vaccine,[5] GSK). In clinical trials, HEV 239 and T = 1 VLP conferred comparable hepatitis E protection in vaccine recipients.[5,7] In terms of nanoscale molecules used for antigen presenting cell processes, VLPs were verified to be the key characteristics for immune recognition.[17,18] Based on this, successful recombinant vaccines for hepatitis B and human papillomavirus were brought to market.[17,18] Thus, HEV 239 was considered for further preclinical study as a HEV vaccine.

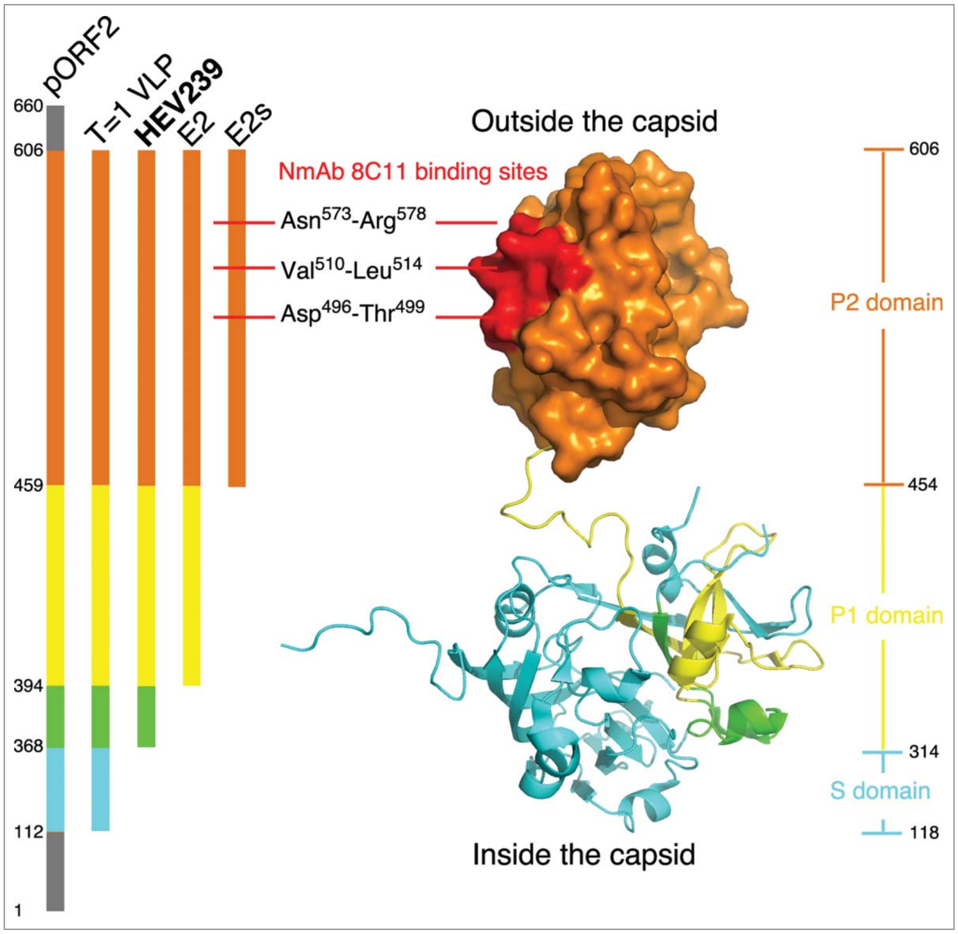

Figure 1. Structural interpretation for HEV 239 vaccine. The structure of HEV ORF2 aa112–606 is rendering in surface mode (P2 domain) and cartoon mode (P1 and S domain), colored by key regions for several HEV historic constructs (left panel), i.e., aa112–367 in cyan, aa368–393 in green, aa394–458 in yellow and aa459–606 in orange. To elucidate the spatial configuration, 3 crystal structures were in superimposition to demonstrate major neutralization sites (Neutralizing mAb 8C11 binding sites colored in red, by PDB (protein database) no. 3RKD), outmost protrusion domain (E2s domain in orange surface, by PDB no. 3GGQ) and P1&S domains (contributing for virus capsid assembly, by PDB no. 3HAG). The figure was prepared by the program PyMol.

The preclinical development of HEV 239 vaccine

HEV 239 was over expressed under the regulatory of T7 promoter in *E. coli*, the gene was cloned into a non-fusion plasmid vector pTO-T7 and subsequent expression was induced by IPTG. HEV 239 forms inclusion bodies in bacteria. These inclusion bodies were harvested by liquid-solid separation and panwashing with Triton-X100 before chaotropic agent denaturation. After harvesting, the resulting ~70% pure HEV 239 inclusion bodies were dissolved in 4 M urea. The HEV 239 protein was further purified to a final purity of 95–98% by 2 polishing chromatography steps and then subjected to particle reassembly with a scalable tangential flow technique, using a membrane cassette with a cutoff size of 30kD.[16] The reassembly condition was optimized for a robust range of pH, ion-strength and temperature. Essentially, HEV 239 can self-assemble in 4 M urea in the presence of salt, which facilitates the assembly control during this process.[19] Self-assembled HEV 239 was further fractionalized using capture chromatography, and the component with an average radius of ~10 nm was collected and absorbed onto an aluminum adjuvant.[16]

The pilot process scale was developed in 10 L fermentation batches, which generated several thousands of vials of vaccine for investigational new drug (IND) purposes. Briefly, the conditions for the serial Essentially, HEV 239 processing were gauged using a variety of biochemical and biophysical approaches, including SDS-PAGE, Western blotting, DLS (Dynamic Light Scattering), SEC HPLC (Size-Exclusion Chromatography), AFM (Atom Force Microscopy), AUC (Analytical Ultracentrifugation), DSC (Differential Scanning Calorimetry) and TEM (Transmission Electronic Microscopy).[20] Antigenicity was monitored using a sandwich ELISA with mAbs 8C11 and 8H3. This mAb couple identified the E2s moiety of HEV 239 on the groove region of the E2s crystal structure.[13] As a rare event in virology, the binding of 8C11 with an antigen will significantly enhance the binding affinity of another mAb 8H3 by 2 log in SPR (Surface Plasmon Resonance) assay. The synergistic action of this mAb couple also was discernible in authentic HEV.[15] All residual contaminants were evaluated and quantified under the regulatory limits issued by the China Food and Drug Administration (CFDA). The immunogenicity of the formulated HEV 239 was measured *in vivo* with the ED_{50} (50% effective dose) test in mice and with the anti-HEV levels in rhesus monkeys. The ED_{50} value for HEV 239 in mice was approximately 0.05 μg, demonstrating that HEV 239 has a high level of immunogenicity. Indeed, the immunogenicity of HEV 239 was 200 times greater than that of the E2 protein.[16,21] The protection efficacy of HEV 239 was primarily evaluated in the rhesus monkey model. Two doses of 5 μg, 10 μg or 20 μg HEV 239 were administered 4 weeks apart. The induced antibody response peaked at week 7 in all 3 dosage groups with comparable antibody titers of around 1384 IU. The anti-HEV levels were measured by ELISA assay and calibrated against a World Health Organization (WHO) reference standard for anti-HEV (National Institute for Biological Standards and Control, NIBSC catalog no. 95/584), which was obtained from an recovered hepatitis E patients with an arbitrary assigned value of 100 IU.[16] The monkeys were then challenged with 10^4 or 10^7 genome equivalences of homologous HEV (genotype 1) or heterologous HEV (genotype 4). All of the HEV 239 vaccinated monkeys ($n = 24$) were completely protected from symptomatic hepatitis E and were also completely protected from subclinical infection by 10^4 HEV ($n = 12$). When challenged with 10^7 HEV, 9 of the 12 monkeys (75%) were protected from subclinical infection. Among the 3 monkeys with breakthrough HEV infection, 2 monkeys (with anti-HEV level of 368 IU and 196 IU) shed virus during the first week post infection and the third monkey (anti-HEV level 961 IU) had detectable HEV RNA in feces during week 3. The vaccine protection efficacy against homologous HEV (genotype 1) or heterologous HEV (genotype 4) infection was similar.[16] After the further safety evaluation of HEV 239 in animals, which including intramuscular irritation in rabbits, acute toxicity testing in KM (Kunming) mice, deformity testing in gravid white KM mice and repetitive immune toxicity testing in SD (Sprague dawley) rats, the HEV 239 vaccine was approved by the CFDA for further clinical trials.[8,22]

Assessment the HEV 239 vaccine critical quality attributes (CQAs)

The product consistency of the HEV 239[8,20,23] vaccine was demonstrated using a combination of biophysical, biochemical and immunochemical methods. Results from these methods demonstrated that different vaccine batches have comparable antigen characteristics or CQAs.

The presence of clinically relevant epitopes can be used as a surrogate marker for vaccine potentcy.[17,24,25] A large panel of monoclonal antibodies (mAbs) against the HEV capsid protein were developed to improve the understanding of HEV virology and to analyze the CQAs of the vaccine during bioprocessing and in the lot release and stability testing.[14,15,20,26,27] Key epitopes of the particulate antigen were analyzed using a panel of murine anti-HEV mAbs against different epitopes, analogous to the approach used for other vaccines.[24,25,28-31] Epitope mapping using cross-inhibitory ELISA, surface plasmon resonance biosensor chip based binding assay, and sandwich ELISA using HEV 239 specific mAbs were used to assure vaccine potency.[20,26,27] Overall, our findings showed that the antigen production process is robust and scalable in Hecolin® manufacturing.

A successful and robust scale-up (i.e., 50-fold) in the production process (1.0 L, 10 L and 50 L) was demonstrated.[20] Multiple HEV 239 batches were produced at a commercial scale (50 L) and were characterized using several different methods (**Table 2**).

Biochemical methods

To verify the consistency of the primary amino acid sequence, analyses were carried out to determine the antigen purity, antigen integrity, molecular weight, pI and protein sequence.[20,27] The most prominent band on the SDS-PAGE gel showed an apparent molecular weight of 29.4 kDa. All three lots exhibited similar MWs by MALDI-TOF-MS, with a mean MW of 25,561.5 ± 1.5 Da (**Table 1**), which is consistent with the theoretical MW of HEV 239. In addition, LC-MS-based protein mapping with tryptic digestion was used to determine the peptide sequence.

Table 2. Analytical toolbox for the comprehensive characterization of a recombinant HEV 239 antigen to demonstrate the process reproducibility and product consistency during Hecolin® production.[20,26,27]

Method		
Biochemical methods	Characteristics	Parameters of HEV 239 or Notes (from multiple lots, n = 6)
SDS-PAGE	Purity, integrity, molecular weight (kDa)	29.32 ± 0 .08
MALDI-TOF MS	Molecular weight (Da)	25,561.64 ± 1 .37
LC-MS	Peptide mapping (coverage, %)	100 (3 lots)
icIEF	pI, whole column detection capillary isoelectric focusing	6.55 ± 0 .03
Biophysical methods		
HPSEC	Size (as reflected by retention time, min)[b]	14.02 ± 0 .08
TEM	Size, morphology	20–30 nm particles with certain degree of irregularity
DLS	Hydrodynamic diameter (nm)	28.92 ± 0 .20
AUC	Sedimentation coefficient (S)	21.42 ± 0 .13
DSC	Thermal stability (°C)	75.58 ± 0 .10
Cloud point	Aggregation propensity (°C)	71.83 ± 0 .16
CD	Secondary structure	The secondary structure, including α-helices and β-sheets, is
UV	Trp/Tyr absorption	consistent with the UV spectrum of a globular protein with a maximum absorption wavelength at 280 nm
Immunochemical methods		
SPR With mAbs	affinity to mAbs	The binding activity to 5 mAbs for different batches of aqueous products with the RU(Ag)/ RU(Ab)
Sandwich ELISA[d]	Antigenicity	8C11 (capture) and 8H3 (detection) to analyze the consistency of the antigenicity among different batches of HEV 239 aqueous products
Immunological assessment		
Mouse potency	Immunogenicity ED_{50} (μg)	0.025–0.060

Note: 1. For product lot release of prefilled syringe, mouse potency assay is used for lot release (spec < 1.0 μg). Lot release of HEV 239 purity (spec > 95.0%) and molecular weight (spec 27.5 ± 2.6 kDa) by SDS-PAGE was performed on aqueous product batches.

Two. The reported values were calculated from the results on 6 manufacturing lots. These values are representative on process performance since similar values were reported for sizing using DLS and antigenicity test using the results from over 20 lots.[20]

The overall amino acid sequence was confirmed with 100% coverage for all 3 batches.[20]

Biophysical methods

Four different sizing methods (TEM, HPSEC, AUC and DLS) were used to monitor the particle size consistency (**Table 1**). The HEV 239-based VLPs were found to be 20–30 nm in diameter by TEM, with a certain degree of irregularity and heterogeneity.[20] HPSEC analysis resulted in nearly identical retention time for all 6 lots of HEV 239 aqueous products.[20] The AUC profiles demonstrated highly similar sedimentation properties for the 6 different lots, all of which peaked at approximately 21.5 s.[20]

Both circular dichroism and UV spectroscopy methods verified the consistency in the secondary and tertiary protein structure among the different HEV 239 lots.[20]

The thermal unfolding of the VLP antigen was analyzed using DSC by monitoring the T_m values of all HEV 239 lots, all of which ranged from ~75–76°C. These results showed good cross lot product consistency as reflected by the thermal stability of the recombinant protein antigen during heat-induced unfolding.[20,27] In addition, the propensity for the protein to aggregate under thermal stress was assessed using cloud point analysis. The heat-induced unfolding or aggregation profiles of the VLPs were highly comparable among all 6 lots, as determined by both DSC and cloud point (**Table 2**).

Immunochemical methods

The *in vitro* antigenicity of an antigen, as probed with different mAbs, correlates in general to the *in vivo* immunogenicity of a vaccine.[30-33] Therefore, a one-site binding and label-free assay (i.e., surface plasmon resonance or SPR)[34-36] and a 2-site binding assay (i.e., a sandwich ELISA)[30,31,33] were carried out to evaluate the antibody binding activity of the HEV 239 antigen.

The label-free and real time sensor chip-based SPR method was used with 5 mAbs recognizing different epitopes (mouse IgGs-8C11, 8H3, 13D8, 12A10 and 16D7) to assess the immunoreactivity of the different batches.[20] A sandwich ELISA was implemented in a manufacturing setting with the desired robustness and reproducibility to show product consistency.[20] A well-characterized neutralizing and protective mAb, 8C11, was selected as the capture antibody,[26] and 8H3 labeled with HRP was used as the detection antibody.

Immunological assessment

To measure the *in vivo* potency of the vaccine immunogenicity, 6 batches of HEV 239 were evaluated by measuring the ED_{50} in a mouse model after absorption onto an amorphous aluminum-based adjuvant. All six batches had comparable ED_{50} values in the range of 0.025–0.060 μg (**Table 2**). Two of the assays used here, the SDS-PAGE and the mouse potency assay (ED_{50} determination), are used for routine lot release testing on the final vaccine formulation and filled product. Based on assay results on recovered antigen, full antigen recovery was observed post adjuvant dissolution with no alterations on antigen characteristics.[27]

Clinical development of HEV 239

All pre-approval clinical trials were carried out in China in accordance with guidelines and regulations issued by the CFDA and the provisions of the Declaration of Helsinki.

Efficacy of HEV 239

A randomized, double-blind, placebo-controlled, single-center Phase III clinical trial was conducted to assess the efficacy of the HEV 239 vaccine against symptomatic hepatitis E. Participants aged 16–65 ($n = 112\ 604$) were randomly assigned to receive 30 μg HEV 239 (absorbed to 0.8 mg of aluminum hydroxide suspended in 0.5 mL of buffered saline) or 5 μg of the hepatitis B vaccine control intramuscularly at 0, 1, and 6 months. The patients were followed for 19 months,[7] and symptomatic hepatitis E cases were identified though a sensitive surveillance system containing 205 local sentinels at the site. The efficacy was demonstrated to be 100% (95% CI, 72–100) in participants receiving all 3 doses of the HEV 239 vaccine or the control vaccine (PPS, per-protocol set) during the following 12 months, starting at 30 d after the receipt of the final dose (7 m–18 m). In the PPS cohorts, no HEV 239 vaccine recipients contracted hepatitis E, whereas 15 hepatitis E cases developed in the control group during the same year. For those who received at least one dose (ITT, intention to treat cohort), the efficacy was 96% (95% CI, 66–99) during the first 18 months.

In an extended efficacy study,[37] all participants in the Phase III trial were followed for another 3 y using the same local hepatitis surveillance system used during the Phase III trial. The long-term efficacy of HEV 239 for up to 4.5 y was demonstrated to be 93% (95% CI, 79 - 98) in the PPS cohort and 87% (95% CI, 71 - 94) in the ITT cohort. Due to the large cohorts of the Phase III trial, only participants in the immunogenicity subset were tested for anti-HEV IgG level at month 7, and as there had been no breakthrough hepatitis E cases in this immunogenicity subset with known anti-HEV level at month 7 until now, the protective level of anti-HEV can not be calculated.

As expected, 90% of the 29 HEV isolates from the identified hepatitis E patients were of genotype 4, which is the predominant HEV genotype circulating in China. The high efficacy of HEV 239, which is derived from HEV genotype 1, against HEV genotype 4 infection supported the concept that a hepatitis E vaccine containing one genotype might protect against infection from different HEV genotypes, which are capable of infecting mammals and share the same serotype.

The HEV 239 vaccine has also been shown to be effective in the prevention of subclinical HEV infection.[6,38] Asymptomatic HEV infection was identified by comparing paired serum samples from the same participant collected at 12 month intervals, starting 30 d after administration of the final dose when the antibody levels were supposed to have peaked. If the anti-HEV IgG level rose from negative to 0.154 Wu/mL (twice of the cut-off level) or increased by 4-fold or greater, patients were considered to have asymptomatic infection. The relative risk of HEV infection in the vaccine recipients decreased with increases in the anti-HEV IgG titer at month 7. Even marginal concentration of antibodies significantly lowered the infection risk. This might explain why the efficacy against subclinical HEV infection is similar in the PPS (79%) and ITT cohorts (77%).[38] Similar efficacy rates had been demonstrated in the Phase II trial, regardless of whether 3 doses (given at 0, 1 and 6 m) or 2 doses (given at 0, 1 and 6 m) of vaccine were given. In both groups, the tested vaccine contains only 20 μg of the HEV 239 antigen.

The administration of 2 doses of HEV 239 given at months 0 and 1 yielded efficacy rates of 100% (95% CI, 9–100) against hepatitis E during months 2 to 6, before the third shot.[7] These data justify the possibility of emergency vaccination during epidemics. Similarly, 2 doses of HEV 239 vaccine given at one month intervals provided satisfying protection against subclinical HEV infection for at least the following 5 months.[6]

Immunogenicity of HEV 239

HEV 239 administration induced a vigorous anti-HEV IgG response in vaccine recipients, regardless of their initial antibody status. Of the baseline seronegative participants, 99.9% had seroconverted one month after the full vaccination course (7 m), and 87% remained seropositive at month 55. The geometric mean concentration (GMC) of antibody dropped quickly from a peak of 14.96 Wu/ml at month 7, which is higher than the level induced by natural HEV infection (0.6 Wu/ml) but lower than that induced after symptomatic hepatitis E disease (80.9 Wu/ml), to 1.47 Wu/ml for the first year.[37,38] The concentration then slowly decreased to 0.27 Wu/ml by month 55. Although the antibody decayed to a relative low level at this time point, the long-term efficacy until month 54 is still as high as 93% (95% CI, 79–98) in the PPS cohort, the need and timing for a booster dose of HEV 239 remains to be further investigated. For participants with pre-existing antibodies, the antibody response is more robust and sustained, with little difference between those who received 1, 2 or 3 doses of HEV 239 vaccine. This finding suggests that people with pre-existing HEV antibodies would benefit from even a single dose of the HEV 239 vaccine.[7,37] In a HBsAg positive cohort, the immunogenicity of HEV 239 was found to be similar to that of the general population.[39]

Anti-HEV IgG levels induced by different dosage and immunization schedules of the HEV 239 vaccine were also evaluated in the Phase II trial, in which only subjects who were anti-HEV seronegative at baseline were enrolled. All participants who received 3 doses of the HEV 239 vaccine seroconverted by month 7, and the level of immune response increased as the dosage increase from 10 μg to 40 μg. The difference in the geometric mean antibody concentration (GMC) was significant between the 30 μg and the other higher doses ($p < 0.05$). However, the difference in the GMC between 20, 30 and 40 μg was not statistically significant. The study found that the 3 doses course was more potent than the 2 doses course.[6]

Safety of HEV 239

The data from all clinical trials suggest that the HEV 239 vaccine is well tolerated.[40] In the Phase I trial, 44 healthy Chinese adults were enrolled, and all were anti-HEV IgG seronegative with normal serum biochemistry values. Then, 20 μg of the HEV 239 vaccine was administered at month 0 and 1. All participants were followed for 60 d after the first dose, and their serum biochemistry values were analyzed at day 0 and 60. No serious adverse events were reported. Furthermore, the serum biochemistry values of the participants, including fibrinogen (FBG), urea nitrogen (UREA), glucose (GLU), alanine aminotransferase (ALT), showed no abnormal changes from their baseline values by day 60.[8]

The Phase III clinical trial had 112,604 participants. In this trial, data obtained from the "reactogenicity subset" (n = 2645) within the first 72 hours following each dose showed the occurrence of more frequent local adverse events in the HEV 239 group (13.5%) compared to the control hepatitis B vaccine group (7.1%). This might be partially due to the higher antigen dose in the HEV 239 vaccine (30 μg) than the hepatitis B vaccine (5 μg). Local adverse events of level 3 or higher, solicited systemic adverse events and unsolicited adverse events occurred at similar rates between the study groups. Serious adverse event (SAE) data were collected for all 112,604 participants and categorized according to the Medical Dictionary for Regulatory Activities (MedDRA). During the Phase III trial and the extended 4.5-year follow-up period, a comparable number of participants in both the vaccine and placebo groups experienced SAEs. None of the SAEs were believed to be related to the vaccination.[7,37]

There were 37 women in the HEV 239 vaccine group and 31 women in the control group who were inadvertently administered the vaccine during pregnancy.[41] The rates of adverse events observed in the pregnant women were similar to those observed in matched non-pregnant women. The weights, body lengths and gestational ages of the newborns were comparable in both groups. Although this sample size is small and further study is needed, these data preliminarily suggest that the HEV 239 vaccine is well-tolerated in pregnant women. The safety of HEV 239 was also evaluated in HBsAg positive persons, and the resulting data are reassuring.[39]

Future Challenges

To date, Hecolin® is only available in the Chinese market and been approved for use in people older than 16 years, it is indicated for vaccinating individuals at high risk of HEV infection, such as those involved in animal husbandry, students, members of the armed forces, food-handlers, women of childbearing age, and travelers to endemic regions. The Chinese CDC has an online reporting system to collect post-marketing adverse reactions/events, and this body has not identified any safety concerns with the vaccine. Although the existing 4.5 y of safety and efficacy data for Hecolin® are reassuring, data has not yet been collected in some special populations, including as pediatric subjects (< 16 y of age), the elderly (> 65 y of age), pregnant women, persons with underlying liver diseases or those who are immunosuppressed. These groups face a greater threat of HEV infection and are therefore in more urgent need of this vaccine.

On the other hand, although epidemics of hepatitis E with thousands of cases and hundreds or tens of deaths occurred now and then in low-resource countries, HEV 239 vaccine are not available to these people until it be prequalified by WHO. The deep gap between the vaccine and those who are in urgent need of this vaccine still waits to be filled.[42]

In conclusion, the availability of Hecolin® represents an important milestone in the control and prevention of HEV. However, there is still long way to go.

Disclosure of Potential Conflicts of Interest

No potential conflicts of interest were disclosed.

ABSTRACT

Background: Genetic risk factors for dengue hemorrhagic fever/dengue shock syndrome (DHF/DSS) and dengue fever (DF) are limited, in particular there are sparse data on genetic risk across diverse populations.
Methods: We conducted a genome-wide association study (GWAS) in a derivation and validation sample of 7,460 participants of Latin American, South Asian, and South East Asian ancestries. We then developed a weighted polygenic risk score (PRS) for each participant in each of the validation cohorts of the three ancestries to predict the risk of DHF/DSS compared to DF, DHF/DSS compared to controls, and, DF compared to controls.
Findings: The risk of DHF/DSS was significantly increased, odds ratio [OR] 1.84 (95%CI 1.47 to 2.31) (195 SNPs), compared to DF, fourth PRS quartile versus first quartile, in the validation cohort. The risk of DHF/DSS compared to controls was increased (OR=3.94; 95% CI 2.84 to 5.45) (278 SNPs), as was the risk of DF compared to controls (OR=1.97; 95%CI 1.63 to 2.39) (251 SNPs). Risk increased in a dose-dependent manner with increase in quartiles of PRS across comparisons. Significant associations persisted for PRS built within ancestries and applied to the same or different ancestries as well as for PRS built for one outcome (DHF/DSS or DF) and applied to the other.

Interpretation: There is a strong genetic effect that predisposes to risk of DHF/DSS and DF. The genetic risk for DHF/DSS is higher than that for DF when compared to controls, and this effect persists across multiple ancestries.

Research in Context

Evidence before this study

We conducted a literature review on MEDLINE in January 2013 before conducting this study on genetic determinants of dengue and did not find a systematic review. We found narrative reviews and individual candidate gene studies. Over the course of the study and after completion we updated our search (last search, November 5, 2018). We identified candidate gene studies but only one GWAS study in a Vietnamese population, replicated in a Vietnamese and in a Thai population, demonstrating as association between variants in major histocompatibility complex (MHC) class I polypeptide-related sequence B (*MICB)* and phospholipase C, epsilon 1 (*PLCE1)* and DSS. We did not identify any studies addressing polygenic risk for dengue.

Added value of this study

This study demonstrates a strong polygenic risk for dengue that applies across different ancestries. The polygenic risk derived from one syndrome predicted risk in the validation cohort of another syndrome.

Implications of all the available evidence

In certain populations, specific genetic variants are associated with severe complications of dengue. However, there is genetic susceptibility that is universal, that is, the same alleles increase or reduce susceptibility in diverse regions of the world. This is suggestive of a more general immune mechanism rather than adaptation to DENV-specific strain effects, which would be expected given the large geographical distribution of participants. Moreover, the effect of a similar risk when a polygenic risk score is derived from one syndrome and applied to the other, suggests a common pathological mechanism.

1. Introduction

Infection with dengue virus (DENV), a mosquito-borne flavivirus infection, is of major global public health relevance [1]. Dengue fever (DF), or “break-bone fever”, is characterized by fever, headache, retro-ocular, and joint pain, rash, and, lymphadenopathy [2]. In less than 2% of those infected for a second time, the disease may progress to dengue hemorrhagic fever characterized by thrombocytopenia and vascular leakage and dengue shock syndrome (DSS) (DHF with evidence of systemic hypoperfusion) [3–8]. A secondary heterologous infection, that is infection with a DENV serotype different from that of prior infection, can increase risk of DHF/DSS through antibody-dependent enhancement [9,10]. However, given that only a small proportion of secondary infections result in severe disease, underlying genetic predisposition is likely [11].

The vast majority of genetic studies for dengue have been candidate gene studies, where a number of genetic variants, including single nucleotide polymorphisms and HLA polymorphisms, have been implicated as genetic risk factors [12–19]. Existing data have been conflicting [20]. There has only been one genome-wide association study (GWAS) conducted for dengue, which showed an association between variants in major histocompatibility complex (MHC) class I polypeptide-related sequence B (*MICB)* and phospholipase C, epsilon 1 (*PLCE1)* and DSS [21]. However, this study was conducted in a single ancestry population (Vietnamese). Although these variants were replicated when tested alone in another Vietnamese and a Thai population [22,23], less is known about the extent to which genetic variants that predispose for dengue act across ancestries. We report here a GWAS in a sample set with multiple ancestries, which allowed us to test the hypothesis, using polygenic risk scores, that genetic variants across the genome predispose to DHF/DSS and DF.

2. Methods and methods

2.1. Study participants

The Dengue Population Genetics Program (DPGP) was a genetic epidemiologic study where DNA was obtained from participants of three major ancestries from seven countries: Latin American from Honduras, Mexico, Nicaragua, Colombia; South Asian from Sri Lanka; and Southeast Asian from Vietnam and Myanmar between March 2003 and December 2013. Participants were categorized into one of the following groups: DF, DHF/DSS, and controls (definitions are shown in Table S1 in the Supplementary Appendix). Clinical phenotype data was obtained from community cohort studies and hospitalized patients with DHF/DSS and DF. Infection was confirmed by serology, DENV RNA demonstrated by RT-PCR, DENV NS1 antigen detection, or, viral isolation [24, 25]. Controls were defined as participants who had evidence of DENV infection but no evidence of DHF/DSS or DF (they consisted of two groups, a group of 513 that seroconverted during the study and 1706 IgG antibody positive participants). They were derived by flow cytometry-based assays or ELISA in cross-sectional samples of participants who had no symptoms of dengue at the time of testing and had no history of hospitalization for dengue, or annual healthy samples by neutralization assay (using plaque reduction neutralization assay or flow cytometry-based assays) for participants in cohort studies [26, 27]. The analysis included participants with primary and secondary DENV infections. A summary of laboratory testing for infection is provided in Table S2 in the Supplementary Appendix.

2.2. Genotyping

We conducted the study using a two-stage design. In the first stage, we used the Illumina OmniExpress BeadChip array of 958,178 single nucleotide polymorphisms (SNPs) with genome-wide coverage to identify genetic associations in three separate comparisons: DHF/DSS versus DF, DHF/DSS versus controls, and, DF versus controls using a derivation cohort of 2498 subjects. We included genetic variants that had previously been associated with DHF/DSS or DF (e.g., DC-SIGN, vitamin D receptor, Fc gamma receptor II, TNF alpha, IL-10, HLA-A, HLA-B, TAP 1, Tap 2, CTLA-4, *MICB* and, *PLCE1)* in the derivation analyses [11, 21]. In the second stage, SNPs with p-values $\leq$0.0001 for at least one of three comparisons in the analysis of the entire derivation cohort were pruned at the linkage disequilibrium cut-off of r^2=0.20 using a 500 kb window. These, along with the genetic variants previously associated DHF/DSS or DF, were genotyped in a validation (replication) cohort of 6879 subjects using the Illumina GoldenGate BeadXpress platform using a total of 1536 SNPs.

2.3. Quality control

In the overall derivation cohort, samples with <99% call rates and sex mismatch were removed, as were the SNPs with <99% call rate, <1% minor allele frequency (MAF) or Hardy-Weinberg p-value <0.000001 in controls. For the ancestry-specific derivation cohort, we further removed SNPs with MAF <5% because the sample size was limited. In the overall validation cohort, we removed samples with <95% call rates, SNPs with <95% call rate, or SNPs with <1% MAF in order to avoid excluding SNPs that were narrowly < 5%. The quality controls in derivation and validation cohorts were performed using PLINK (version 1.09).

A total of 9377 DNA samples was received for analysis, of which for the derivation cohort 999 were from participants with DHF/DSS, 999 DF, and, 500 were from controls. For the validation cohort, there were 1715 samples from participants with DHF, 2731 DF, and, 2433 controls. Following quality control steps, there were a total of 2248 DNA samples from the derivation phase and 5212 samples from the validation phase with the final dataset consisting of 7460 samples. The characteristics of participants in this final dataset are summarized in Table 1. Of the total of 958,178 SNPs genotyped in the derivation phase, 662,390 met quality control and the MAF criteria, as did 1165 of the 1536 SNPs tagged for the validation phase.

2.4. Association testing and replication

We calculated heritability using Genome Wide Complex Trait Analysis [28]. We used the Grammar-Gamma method to test for the associations of SNPs with DHF/DSS versus DF, DF versus controls, and, DHF/DSS versus controls in the entire derivation cohort (all ancestries), adjusted for age and sex, and population structure was taken into account by the kinship coefficient matrix of the variance component model [29]. The Grammar-Gamma analysis was also performed separately for each derivation sample of Latin American, South Asian, and, Southeast Asian ancestries, where only SNPs with allele frequency ≥5% were analyzed and a heritability coefficient (h^2) of 0.3 was assumed (rather than estimated from the data) in a sample to ease model convergence as ancestry-specific sample sizes were small. We also checked the data for outliers from ancestries other than Latin American, South Asian, and Southeast Asian. We used a significance level of $p<5 \times 10^{-8}$ to account for multiple testing. In the replication cohort, a separate logistic regression model was fitted adjusting for age, sex and ancestry for each SNP for each comparison. In order to exclude the possibility of population stratification, we did the analyses adjusted for principal components.

Table 1
Distribution of participants by age, sex, and ethnicity.

	Ethnicity			
Characteristics	Latin America	South Asia	South East Asia	Total
Derivation cohort				
Control	210	44	151	405

Abbreviation: SD, standard deviation; DF, Dengue fever; DHF, Dengue hemorrhagic fever; DSS, Dengue Shock Syndrome.

2.5. Polygenic risk score analysis

To test for the possibility of polygenic risk for DENV infection outcome (DHF/DSS versus DF, DHF/DSS versus control, and DF versus control), we developed a weighted polygenic risk score (PRS) for each participant in each of the validation cohorts of three ancestries (Latin American, South Asian, Southeast Asian) separately. For each participant, the PRS was the sum of the product of log-odds ratios of a set of SNPs passing a p-value threshold in a derivation cohort and the number of effect alleles at the corresponding SNPs (see Methods section in the Supplementary Appendix). Polygenic risk scores were constructed using all three ancestries (the primary PRS analysis) as well as single ancestries for sensitivity analyses. We also conducted the analysis using five principal components as covariates. If the allele at a SNP for a participant was missing, the number of effect alleles was imputed using the average number of effect alleles in all participants within the same ancestry with the same outcome. Nine different p-value thresholds ranging from 0.1 to 0.00001 were used for selecting SNPs to compute PRSs. All SNPs had a p-value < 0.001 for at least one analysis but could have had larger p-values for other comparisons.

2.6. Overall effect

To test the association of PRS with each of three comparisons (DHF/DSS versus DF, DHF/DSS versus controls and DF versus controls), first a logistic regression model was fitted by comparing the second to fourth quartile PRS to the first (referent), adjusting for age and sex in each validation ancestry. Based on plots of the p-value threshold and effect size for selecting SNPs for the PRS, which remained similar from a range of 0.1 to 0.001, we selected a p-value of 0.01 for the PRS (Figure S1 in the Supplementary Appendix). To assess the association of PRS in the overall validation cohort (overall effect), the results (the log-odds ratios and corresponding standard errors) from all three ancestries were then pooled using the fixed-effect model of meta-analysis. We also conducted a similar set of analyses by demonstrating the effect using a standardized PRS (i.e., PRS divided by its standard deviation, SD) adjusting for age and sex in each validation ancestry.

2.7. Secondary analyses

We conducted secondary analyses using derivation and validation cohorts of different ancestries. We examined 1) the effect of a PRS derived from all three ancestries and applied to a validation cohort of a single ancestry, 2) the effect of a PRS from the derivation cohort of a single ancestry applied to the validation cohort of the same ancestry, 3) the association of PRS from one derivation ancestry applied to a validation cohort of two different ancestries, 4) the effect of PRS derived from one single ancestry applied to a validation cohort of all ancestries, 5) a PRS from the derivation cohort of either DHF/DSS versus control or DF versus control then applied to the validation cohort of the other syndrome comparison. We examined these using a standardized PRS with the OR expressed per change in SD or by comparing quartiles.

The Grammar-Gamma analyses were performed using the R package GenABEL (version 1.8–0). Statistical Gene score analyses were performed using R software, version 3.2.4.

2.8. Role of the funding source

The study sponsor played no role in study design; in the collection, analysis, and interpretation of data; in the writing of the report; nor in the decision to submit the paper for publication.

2.9. Ethics statement

This study was approved by the McMaster research ethics board and that of all participating institutions. Participants provided informed consent for the analyses done in this study.

3. Results

3.1. Heritability estimates

By testing for chip-wide heritability, that is, the portion of the phenotypic variation that can be explained by genotyped genetic markers [30], overall and by ancestry, we found significant values for DHF/DSS compared to DF for Latin Americans and Southeast Asians (0.18 and 0.21), for DHF/DSS compared to controls for Latin Americans, South Asians, and Southeast Asians (0.35, 0.21, 0.18 respectively), and, for DF compared to controls for Latin Americans and Southeast Asians (0.20 and 0.56 respectively), all p-values <0.05. The establishment of such heritability supported testing for genetic risk of variants.

3.2. Association testing

In the analysis of the entire derivation sample, none of the SNPs reached the significance level of $p<5 \times 10^{-8}$ for any comparison (Figure S2, Table S3 in the Supplementary Appendix). For the DHF/DSS versus DF comparison, the top associated SNP in the meta-analysis of derivation and replication phases was rs6675033 with p-value of 2.40×10^{-7} near the transcriptional adapter 1 (*TADA1*) gene on Chromosome 1 (Table S3), where the association was observed only in the derivation but not in replication sample. Genetic variants tested that had previously been found associated with DHF/DSS or DF (DC-SIGN, vitamin D receptor, Fc gamma receptor II,TNF alpha, IL-10, HLA-A, HLA-B, TAP 1, Tap 2, CTLA-4, *MICB* and *PLCE1*) did not reach the pre-specified significance in the derivation analysis and were not replicated. Including ancestry as a co-variate did not change the results. We also conducted the genome-wide analysis separately in a meta-analysis setting, including using ancestry specific principal components, and the findings remained similar. The presence of significant heritability yet no genome-wide significance suggested a polygenic model. On this basis, we tested a PRS.

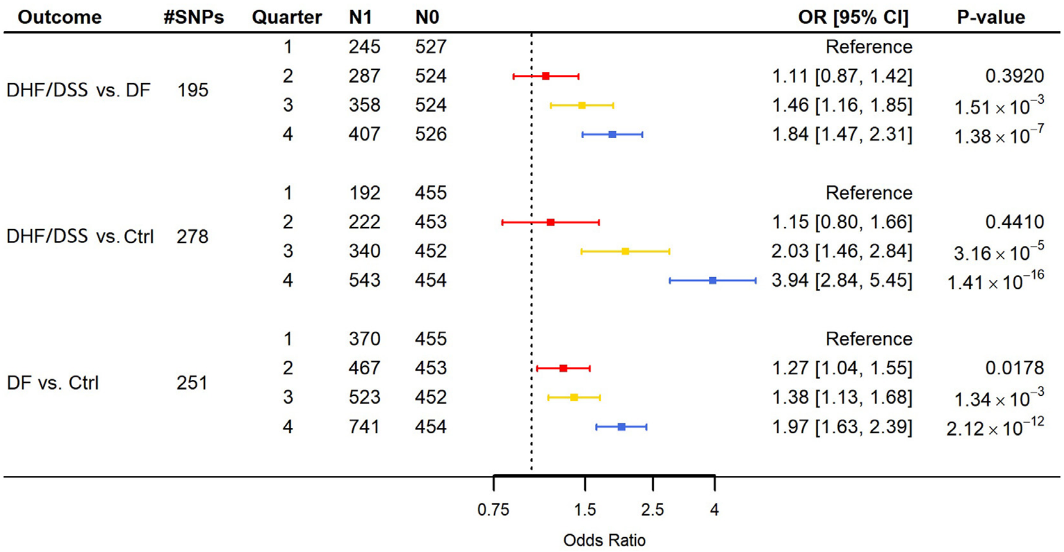
3.3. Polygenic risk score

The risk of DHF/DSS was significantly increased, odds ratio [OR] 1.84 (95%CI 1.47 to 2.31), p-value 1.38×10^{-7} compared to DF, when the fourth-quartile PRS was compared to the first-quartile PRS (referent) in the validation cohort (Fig. 1). The risk of DHF/DSS compared to controls was increased, OR 3.94 (95% CI 2.84 to 5.45), p-value 1.4×10^{-16}, for the fourth-quartile PRS to reference comparison. Similarly, the risk for DF increased compared to controls, OR 1.97 (95%CI 1.63 to 2.39), p-value 2.12×10^{-12}, fourth-quartile PRS compared to reference. The effect size increased in a dose-dependent manner as the PRS increased, with a highly significant effect for third quartile versus referent comparison for all three outcomes (Fig. 1). Although ORs >1 for the PRS in the second quartile compared to the first was observed for all three outcomes, they were only significant for DF versus controls.

Using a standardized PRS, the results were similar (Table 2, Fig. 2). The effect of PRS using a p-value threshold of 0.01 resulted in the following effects: OR 1.31 (1.20 to 1.42) per SD for DHF/DSS versus DF, p-value 1.95×10^{-11}; OR 1.89 (1.69 to 2.11) per SD for DHF/DSS versus control, p-value $1.49 \times 10^{-33;}$ OR 1.29 (1.21 to 1.38) per SD, DF versus control, p-value 5.80 x 10^{-13}. Using a different p-value threshold of 0.0005 to derive the PRS resulted in similar effect sizes: OR 1.29 (1.19 to 1.40) for DHF/DSS versus DF, p-value 2.50×10^{-10}; OR 1.76 (1.57 to 1.96) for DHF/DSS versus control, p-value 3.87×10^{-27}; OR 1.22 (1.14 to 1.31), DF versus control, p-value 1.28×10^{-8}. The effect size of all p-value thresholds is shown in Figure S1. Our results did not change when we included principal components as covariates.

3.4. Secondary analyses

For each of the three DENV infection outcome comparisons (DHF/DSS versus DF, DHF/DSS versus control, DF versus control), the results of our five secondary analyses were similar in direction and



Outcome	#SNPs	Quarter	N1	N0	OR [95% CI]	P-value

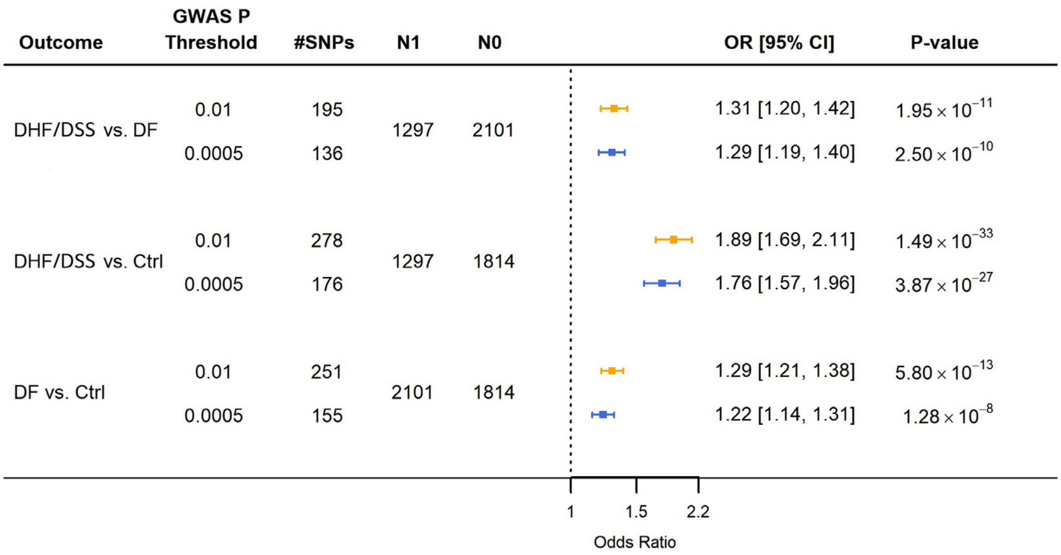
magnitude to our overall effects (Tables S4 -S9, Figures S3-S6). When we derived the PRS from the overall derivation cohort for DF versus control and applied it to a validation cohort for DHF versus control, the effect size was similar to our previous estimates, OR 1.60 (95%CI 1.45 to 1.77), p-value 2×10^{-19} (Table S9). Conversely, when the PRS was derived from DHF/DSS versus control and applied to a validation cohort of DF versus control, the effect was similar, OR 1.37 (95%CI 1.28 to 1.46), p-value 8.45×10^{-19} .

4. Discussion

We found a strong genetic risk, derived from PRS from a multi-ancestry population, when DHF/DSS was compared to DF, DHF/DSS compared to controls, and, DF compared to controls. Moreover, this polygenic risk had a dose effect, with the risk increasing with an increasing number of risk alleles in the PRS. Sensitivity analyses demonstrated that PRS derived from single ancestries and applied to a



Outcome	GWAS P Threshold	#SNPs	N1	N0	OR [95% CI]	P-value

Fig. 2. Forest plot of the associations of polygenic risk scores* quartiles. Notations/abbreviations: N1 and N0, total number of cases and comparisons in overall validation cohort; P, p-value; OR, odds ratio; CI, confidence interval. *Both derivation and validation cohorts were entire samples of all three ancestries of Latin American, South Asian and Southeast Asian. For an outcome, the estimate of odds ratio of each polygenic risk quarter versus the first quarter was obtained by pooling the corresponding log-OR estimates at p threshold of 0.01 across three ancestries using a fixed-effect meta-analysis model.

global validation cohort remained significant predictors of risk, as did multi-ancestry PRS when applied to single ancestries, and single ancestries PRS when applied to the same ancestry in the validation cohort. We also found that PRS derived from one syndrome predicted risk in the validation cohort of another syndrome.

The effect sizes we observed, such as almost a four-fold risk of DHF/DSS compared to controls, are among the highest risk factors reported for dengue [3]. Studies that have tested variants shown to be significant in a GWAS study reported effect sizes that were substantially lower (< 1.5) [21–23]. Even when examining other risk factors for severe dengue, including age, sex, and, nutritional status, our PRS is the strongest risk factor [31]. The large size of this effect is compatible with a polygenic effect for all three DENV infection outcome comparisons, i.e. DHF/DSS versus DF, DHF/DSS versus controls, DF versus controls. In the overall validation cohort of all three ancestries, the evidence of polygenic risk was stronger for DHF/DSS versus control compared to DF versus control when derived from overall or ancestry-specific GWAS cohorts, suggesting that not only the risk is polygenic but also that the risk of more severe complications increases with higher burden of associated genetic variants.

Our secondary analyses, where we derived the polygenic risk scores from one ancestry population or degree of severity of DENV infection to validate in another ancestry or another severity level, indicate that the association of polygenic risk score is indeed robust. Given the polygenic origin of these traits with large numbers of SNPs with very small effects, it is not surprising that our GWAS findings were not replicated, and this may help explain inconsistencies in the results of previous genetic association studies [11]. Importantly, these secondary analyses demonstrate that the genetic susceptibility we observed is universal, that is, the same alleles increase or reduce susceptibility in diverse regions of the world. This is suggestive of a more general immune mechanism rather than adaptation to DENV-specific strain effects, which would be expected given the large geographical distribution of participants. Moreover, the effect of a similar risk when PRS was derived from one syndrome (DHF/DSS or DF) and applied to the other, suggests a common pathological mechanism.

Strengths of this study are the diverse ancestry of participants and the consistency of the findings. We acknowledge that use of participants that had no symptoms at the time of testing and no history of hospitalization as controls may have led to misclassification persons with DF as controls. However, this would have been mitigated by our use of controls with inapparent infection and serological evidence of infection. Any bias would have been towards the null, but the fact that we found an effect suggests that it in fact may have been underestimated. Furthermore, the effect of misclassification of controls in genetic association studies is minimal [32]. Similarly, any variance across community cohort studies for admission trends would be mitigated by using strict phenotype definitions adjudicated centrally. If thresholds for admissions varied for ascertainment of cases, any significant effect that we reported would be more likely to be underestimated in situations where thresholds for admission of DHF or DSS were lower. Moreover, since the main effects are polygenetic, it is very unlikely that admission to hospital would be associated with any such effect. We acknowledge that the power to detect variants significant at the genome-wide level may have been limited. However, the high degree of heritability and robust estimates of risk using the PRS argue strongly in favor of a polygenic model. We also acknowledge, despite the relatively high effect size, that the odds ratios are however modest for public health application.

In summary, our data provide strong evidence that multiple genetic variants confer clinically important risk for both DHF/DSS and DF. To our knowledge, this is the first report to demonstrate such polygenic risk for an infectious disease. Our data offer insight into how genetic variants predispose to dengue as well as the utility of using PRS in the study of infectious diseases.

ABSTRACT Typhoid fever, caused by *Salmonella* Typhi (*S*. Typhi), is a life-threatening disease, usually food-borne and commonly associated with international travel. The disease transmission remains endemic in many low- and middle-income countries, representing further hotspots for seeding new global outbreaks. China has historically been affected by typhoid fever, but the respective roles of local transmission and importation remain unknown. Here, we generated a nationwide map of the typhoid burden in China and investigated the associations between typhoid disease, climate and various socioeconomic parameters. To assess transmission dynamics, we sub-sampled *S*. Typhi isolated within China over five decades and sequenced their genomes. The resulting 705 new genomes, placed in context with 5,190 global isolates from 87 countries on six continents, led to the discovery of several predominant inland Chinese clones belonging to the clades 2.1/2.3/3.2/4.3. These clones were associated with multiple introductions from overseas, followed by local expansion. Notably, 4.3.1 isolates from eastern China were not genetically close to those from northwestern China but to the international isolates, indicating their association with international travel. Additional *in vitro* assays showed that 4.3.1 elaborated better intracellular survival, acid tolerance, and desiccation tolerance than other lineages, partially explaining its success. For the first time, we have probed typhoid transmission in China, finding local transmission and importation, which could guide the policy for typhoid control.

IMPORTANCE Typhoid fever is a life-threatening disease caused by *Salmonella enterica* serovar Typhi, resulting in a significant disease burden across developing countries. Historically, China was very much close to the global epicenter of typhoid, but the role of typhoid transmission within China and among epicenter remains overlooked in previous investigations. By using newly produced genomics on a national scale, we clarify the complex local and global transmission history of such a notorious disease agent in China spanning the most recent five decades, which largely undermines the global public health network.

KEYWORDS *Salmonella* Typhi, typhoidal fever, transmission, exploiting genomics, pandemic clone

Salmonella enterica serovar Typhi (*S*. Typhi) is a human-restricted bacterium that causes typhoid fever. The disease is estimated to cause ~21.7 million illnesses and 216,000 deaths annually (1). Typhoid transmission is known to occur through two modes: "long-cycle" transmission, occurs through long-term exposure to contamination in the broader environment (i.e., untreated water or sewage), whereas "short-cycle" transmission, refers to individuals exposed through close interaction with infected individuals via food handling and is often linked to travel (2). Typically, "long-cycle" transmission occurs in endemic countries with inadequate hygiene and safe food/water handling practices,

including southern Asia, Africa, and South America (1, 3, 4), where the environment is the primary reservoir. In high-income countries with improved sanitation facilities, however, "short-cycle" transmission is dominant, with most cases associated with recent international travel (5), where humans are the main reservoir.

Genetically, *S*. Typhi was traditionally thought to be monophyletic, with limited nucleotide diversity and recombination capability, as revealed by multi-locus sequence typing technology (6–8). With the high resolution of whole-genome sequencing (WGS), the global *S*. Typhi population can be grouped into 5 primary clades and 24 subclades (9, 10). The clade 4.3.1, also termed H58, represents a common genotype that became widely distributed in southern Asia and the Middle East in the 1990s and later spread worldwide (11). Many of the 4.3.1 isolates are characterized by multi-drug resistance (MDR), including resistance against chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole. MDR was primarily driven by the acquisition of IncHI1 plasmids; however, the more recent integration of additional antimicrobial-resistance (AMR) genes and chromosomal point mutations (12, 13) has conferred resistance to fluoroquinolones, third-generation cephalosporins, and azithromycin in 4.3.1 (14–16).

China has vast geographical, meteorological, and economic diversity across its regions. Historically, typhoid fever was rampant across China. Over the past four decades, dramatic socioeconomic advancement has resulted in the overall incidence of typhoid in China dropping to low levels (17–19). Despite this reduction, the spatiotemporal heterogeneity of typhoid across China is unclear. Whether continuous population migration within China has generated heterogeneity in *S*. Typhi or disseminated endemic clones remains obscure. Additionally, transmission routes within China and potential importations have yet to be defined. To date, few large-scale studies have been conducted except for outbreak reports (20–22), and only 26 *S*. Typhi genome sequences from China are publicly available. Here, we amassed a nationwide collection of *S*. Typhi isolates spanning the last five decades and performed genome sequencing. In combination with global contextual genomes, we performed phylodynamic analysis and investigated the population structure and the scale of internal transmission and importation of *S*. Typhi in China.

RESULTS

Variable typhoid across China

The incidence of typhoid fever has continued to decline since 2004 and has remained constant at 0.8 cases per 100,000 persons per year since 2008 (Fig. 1A). The incidence varied between provinces and was generally found to be higher in northwestern and southern China (Fig. 1B). The incidence was correlated with various climatic factors such as temperature, precipitation, and latitude. However, incidence was not strongly associated with per capita gross domestic product (GDP), the number of outbound tourists, or population density (Fig. 1C; Table S1).

We collected the genomes of 731 *S*. Typhi isolates from 19 provinces across China. A global collection of 5,164 genomes retrieved from the public database was also included to provide a global context. The core genome of these isolates had a size of 3.97 Mb, within which a total of 42,702 core-genome single-nucleotide polymorphisms (cgSNPs) were identified. A Bayesian analysis of population structure typing and GenoTyphi, a 58 SNP-based genotyping scheme (9), were performed, respectively, and produced consistent typing results with each other (Fig. S1).

The genotypic structure of the Chinese isolates was distinct between regions. Northern China was dominated by the primary clade 2, while other regions comprised two or three primary clades (Fig. 2A; Fig. S2). At the subclade level, 2.1 (20.8%), 2.3 (14.5%), 3.2 (21.2%), and 4.3 (9.0%) were dominant in China (Fig. 2B). No obvious clonal replacement was observed in any region during the last two decades (Fig. S3).

The demographic features of patients infected by 4.3 differed from those of other clades, with young people and females accounting for a higher proportion than the elders and males (Fig. S4). The division of the 4.3 patients according to the region further

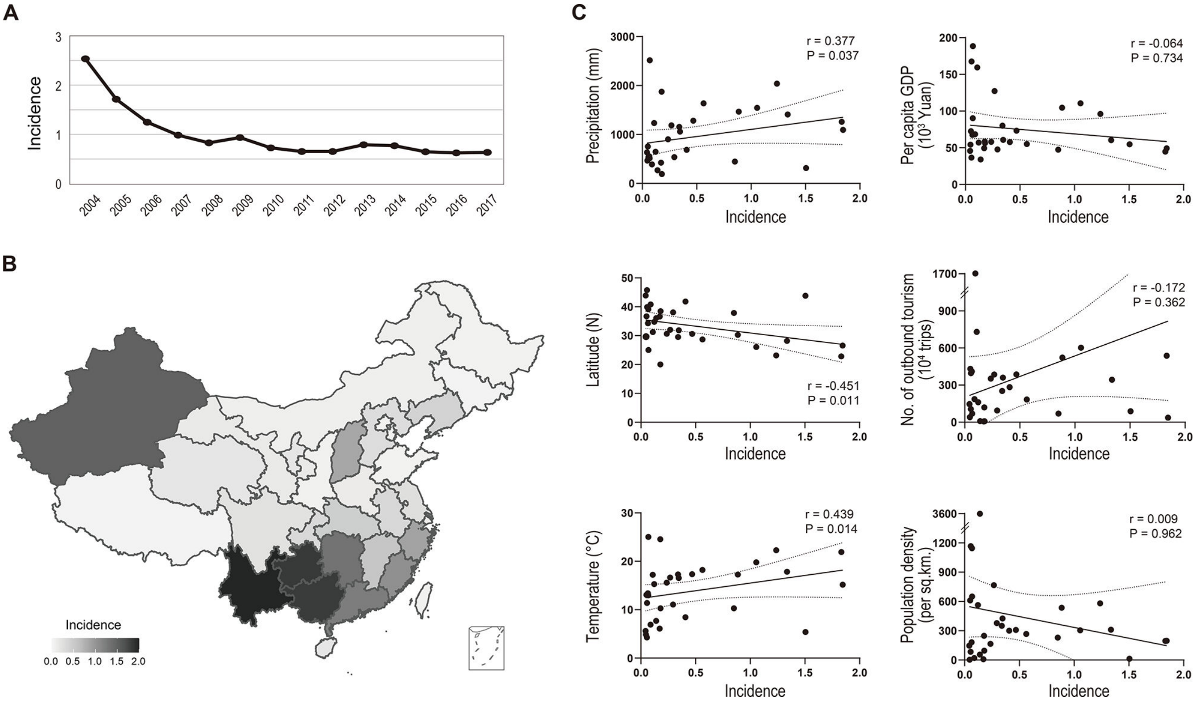

FIG 1 Incidence of typhoid fever in China. (A) Annual incidence (number of cases per 100,000 persons per year) of typhoid fever in China during 2004–2017. (B) The average incidence of typhoid fever in each province of China during 2008–2017. (C) Spearman correlation of climate, social, and economic factors (*y*-axis) with the incidence of typhoid fever (*x*-axis). Each dot indicates a province of China. The data for the plots are appended in Table S1.

showed that the low age of the 4.3 patients was attributable to the patients from eastern China, and the sex bias was attributed to the patients from northwestern China.

International data were obtained from public databases. Overall, Africa, Asia, and Europe were dominated mainly by 4.3 (Fig. 2A and B), although the genotypic composition varied remarkably between and within continents (23).

A low prevalence of AMR *S*. Typhi in China

We further analyzed the distribution of AMR-associated mobile genes and chromosomal mutations, particularly those responsible for resistance to front-line therapy. Only two Chinese *S*. Typhi isolates carried the plasmid-borne *qnr* genes for fluoroquinolone resistance. The *gyr* mutations were present in 12% of isolates and were mainly enriched in the primary clade 4, in which the occurrence was 24%. Three Chinese isolates, which belonged to different clades, carried distinct *bla*$_{\text{CTX-M}}$ gene variants that offered resistance to third-generation cephalosporin. The recently emergent *acrB* mutations that mediate azithromycin resistance, as well as the *mcr*, *tetX*, and carbapenemase-encoding genes, which confer resistance to polymyxin, tigecycline and carbapenem, respectively, were not detected. The rate of plasmid carriage in Chinese isolates was <12% for all primary clades (Fig. 2C), with IncC and IncFIB (pHCM2) as the predominant replicon types (Fig. S5). By comparison, Asian and European isolates were much more resistant than Chinese isolates (Fig. 2C).

Historic “long-cycle” transmission across provinces in China

The clades 2.1, 2.3, 3.2, and 4.3 outnumbered the others. They were frequently recovered from localized provinces over 4 years, indicating their long-term establishment as local reservoirs. To investigate the dates of emergence and geographical transfer of these clades, we verified their temporal structure (Fig. S6) and inferred their timed phylogenies for four major clades (Fig. 3).

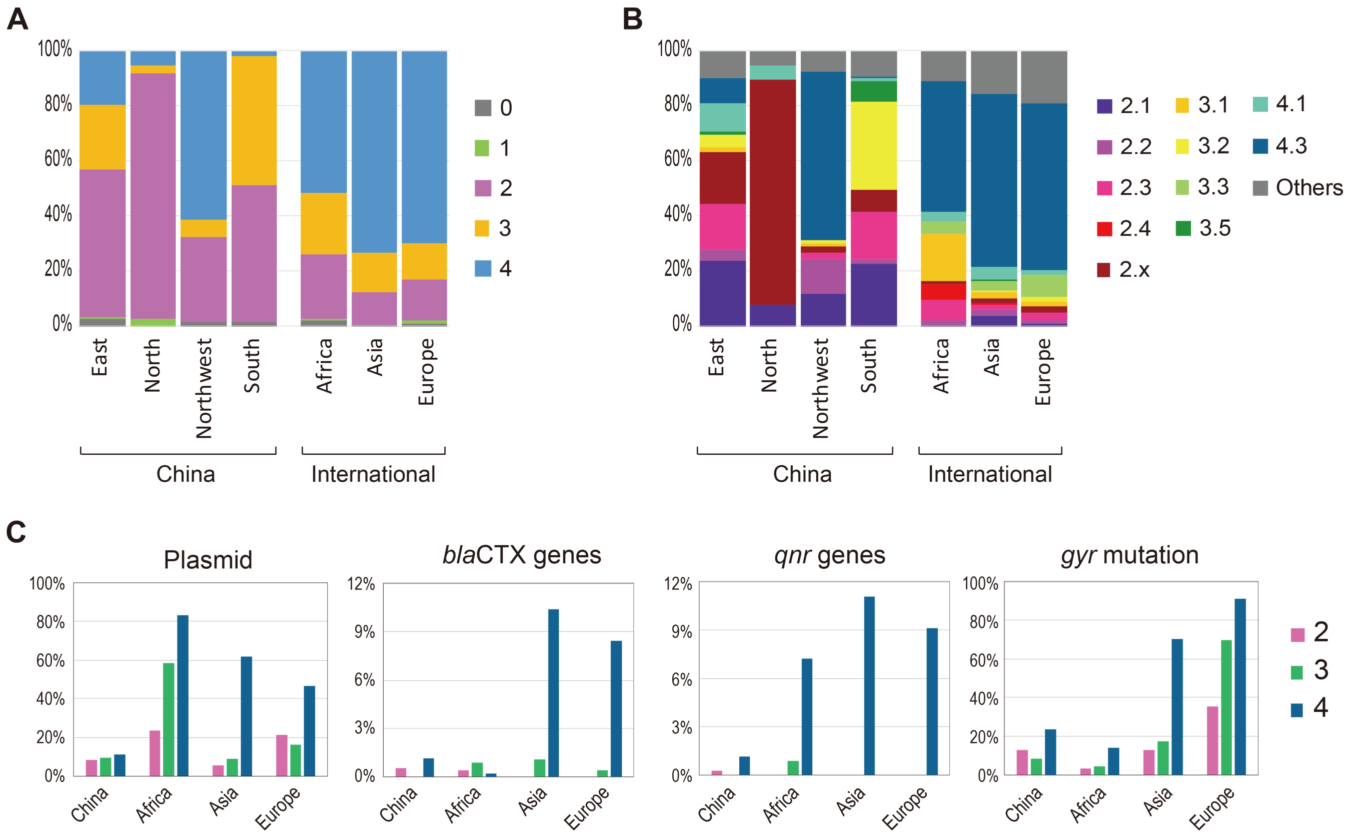

FIG 2 Distinct genotypic and antimicrobial patterns of *S.* Typhi between regions. The *S.* Typhi isolates are grouped into primary clades (A) and subclades (B) by the Genotyphi typing scheme. According to the geographic source, the comparison is made between different parts of China, i.e., eastern (*n* = 144), northern (*n* = 38), northwestern (*n* = 83), southern (*n* = 459), and between various regions over the world, i.e., China (*n* = 731), Africa (*n* = 1,074), Asia (excluding China, *n* = 1,443), and Europe (*n* = 1,942). (C) Comparison of carriage rate of antimicrobial-related genetic determinants.

The profile of geographical origin divided the four clades into two categories (single origin or multiple origin) (Fig. 3A; Fig. S7). The Chinese 3.2 and 4.3 isolates both formed a single branch that separated from the international isolates, indicating a single introduction into China. In contrast, the Chinese 2.1 and 2.3 isolates formed several branches that mixed with international isolates, suggesting that the two clades were introduced into different provinces of China in multiple waves. Notably, 2.3 was found to be repeatedly transmitted into the Guangxi province (in southern China) (Fig. 3A and B). This indicated that, Guangxi, a frontier of Chinese civilization throughout its history and a tourist destination in recent decades, served as a transmission hotspot: the internationally common clones were initially imported into Guangxi and later spread to eastern and northern China (Fig. 3B). Coincidentally, 2.1 and 2.3 entered China much earlier than 3.2 and 4.3. In particular, the establishment of 4.3 as an endemic clone in northwestern China could be traced back to 2002, coinciding with the time that local Muslims frequented the Hajj pilgrimage in the Middle East.

Bayesian estimation of the bacterial population showed a remarkable decline of 2.1, 2.3 and 3.2 since the 1990s (Fig. 3C). Only 4.3 underwent a growth of population, which corresponded to the global dissemination of this lineage.

Recent "short-cycle" transmission within Chinese provinces

As travel-associated cases of *S.* Typhi infections have attracted increasing attention in developed countries (24), we examined putative travel-associated events in China based purely on genome similarity analysis. Except for 4.3, practically all *S.* Typhi isolates in China had their genetically closest relatives collected from the same province. This

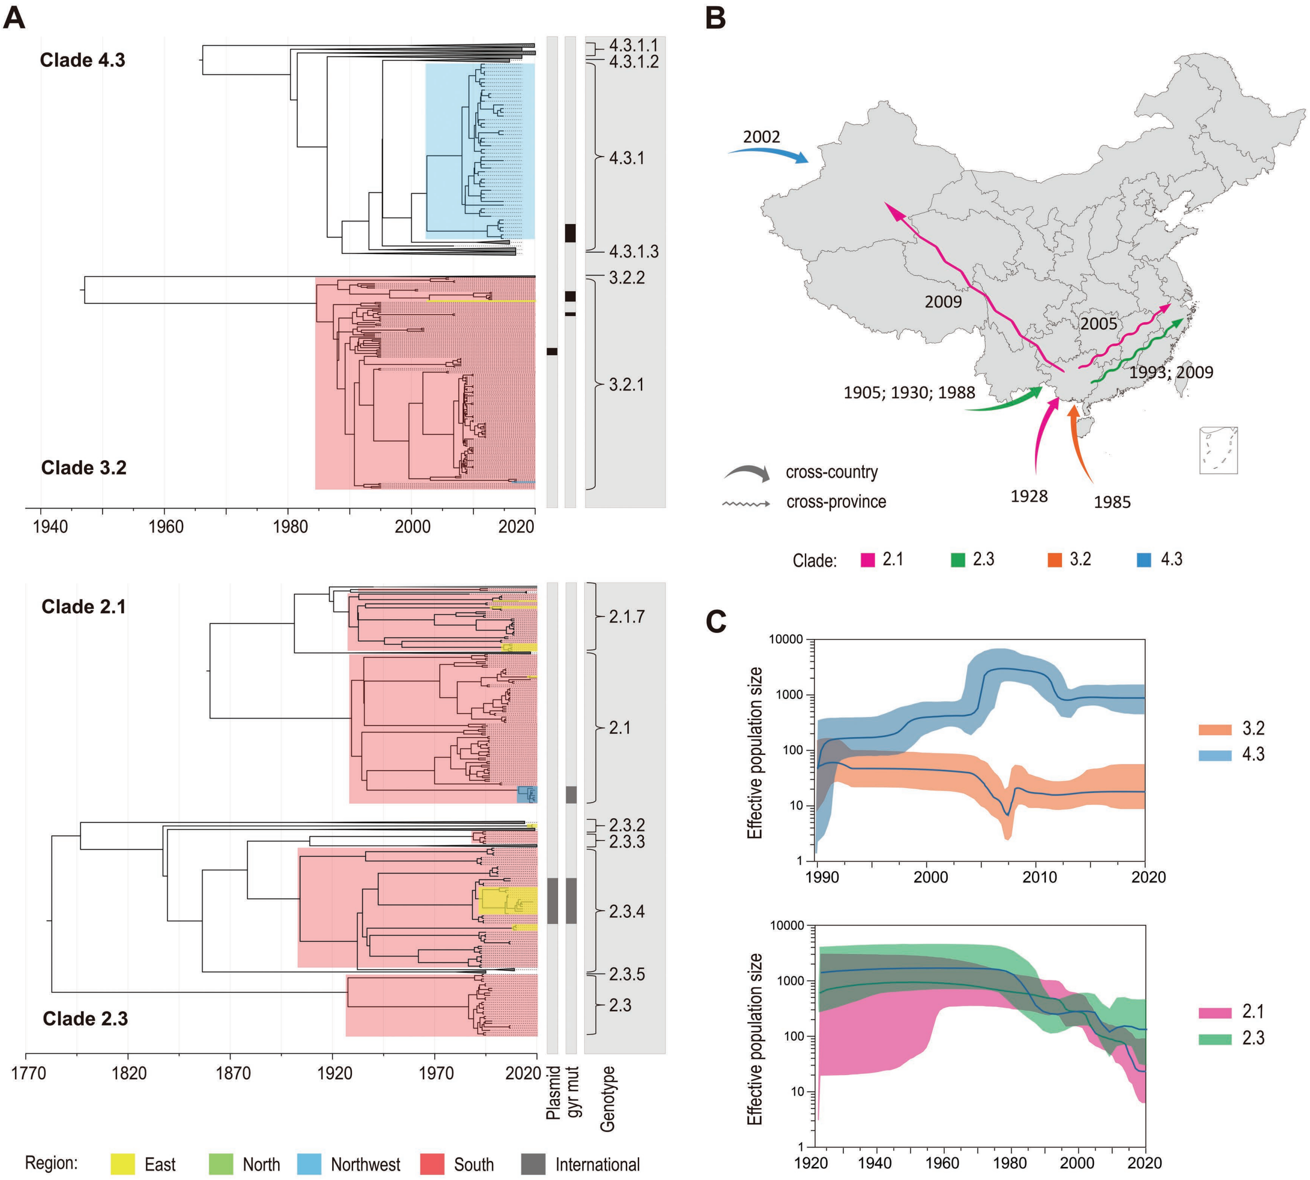

FIG 3 "Long-cycle" transmission of four dominant clades in China. (A) Maximum clade credibility tree (reconstructed using BEAST2) with the antimicrobial-associated metadata. The Chinese *S*. Typhi isolates from four regions are highlighted by boxes in different colors. The branches comprising international isolates are collapsed into triangles in gray. The right columns indicate the presence of plasmid and *gyr* mutations as well as the detailed genotypes. (B) Transmission routes and time inferred by BEAST analysis. Two kinds of arrows show transmission events from abroad and between provinces. The numbers near the arrows indicate the estimated year of the putative transmission events. (C) Bayesian skyline plots show the historical changes in the effective population size of the four clades. Lines and shadings indicate the medians and the 95% HPD intervals of estimated effective population sizes. The *x*-axis shows the time, and the *y*-axis indicates the population size.

finding supports the prevalence of regional endemics in China. Notably, all Chinese 4.3 isolates are 4.3.1. We compared the histogram of the pairwise genetic distance of the isolates within the same province and between different provinces. The former showed a trough between two peaks at five cgSNPs, whereas the latter rose starting from five cgSNPs (Fig. 4A). Based on these findings, we used five cgSNPs as the threshold to determine if the compared isolates belonged to the same episode, resulting in the identification of six instances of cross-province transmission (Fig. 4B). Among them, four involved Guangxi, again demonstrating that Guangxi province has the most frequent within-China transmission events.

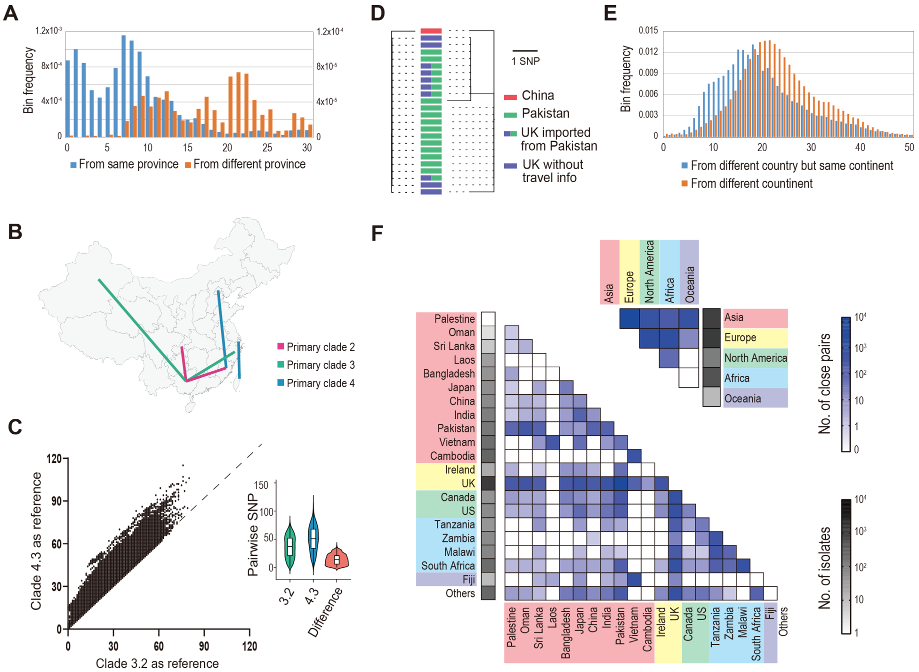

FIG 4 "Short-cycle" (or travel-associated) transmission of *S*. Typhi. (A) Histogram of cgSNP distance for the Chinese *S*. Typhi isolates collected from the same province (left *y*-axis) and different provinces (right *y*-axis). The *x*-axis indicates the number of cgSNPs. (B) Putative transmission events across provinces in China. Each line indicates a pair of *S*. Typhi isolates with pairwise distance <5 cgSNPs, indicating a putative transmission event. (C) Comparison of cgSNP distance between 4.3 isolates derived from different reference genomes as illustrated by a scatter plot and a violin plot, respectively. In the scatter plot, each dot indicates a pair of isolates, with its *x*-axis indicating the cgSNP distance calculated using the genome of strain CT18 (belonging to 3.2) as the reference and its *y*-axis using strain ERL052042 (accession number GCF_001088345, belonging to 4.3) as the reference. In the violin plot, the blue and green violins illustrate the distribution of the two sets of distance; and the red indicates their difference. (D) Example from the Chinese 4.3 isolate 458 (collected from Shanghai city) as well as the isolates of its closest genome match. Using CT18 strain as the reference, the left ML tree shows isolate 458 was one cgSNP distant from the international isolates (from the UK and Pakistan). Using ERL052042 as the reference, the right ML tree shows isolate 458 was one to three cgSNPs distant from these international isolates, but most of the international isolates still have the identical cgSNP profile, i.e., they cannot be distinguished from each other by their pairwise cgSNPs. (E) Histogram of cgSNP distance for 4.3 isolates collected from different countries and continents. The *x*-axis indicates the number of cgSNPs. (F) Genomic relatedness of 4.3 isolates worldwide as revealed by their pairwise cgSNP distance. The heatmaps show the numbers of close cgSNP matches (i.e., <5 cgSNPs) between countries and between continents. Countries with the same shade color belong to the same continents.

The 4.3 isolates collected from eastern China were not genetically closer to those from northwestern China but rather to international isolates (Fig. S7), providing strong evidence of their travel-associated nature. Nevertheless, as the Chinese 4.3 isolates showed an equally small distance from the international isolates from different countries, determining the specific country of origin was challenging. For example, an isolate from Shanghai was diverged from many of the UK and Pakistan isolates by a single cgSNP (Fig. 4D). We attributed this tiny genetic distance to a substantially lower within-clade nucleotide diversity of 4.3 than the other clades (Fig. S8). The calculation of cgSNPs employed the strain CT18 (belonging to 3.2) as the reference, which led to a loss of informative sites within the genomic segments specific to 4.3. Then, we switched to a 4.3 genome as the reference to increase genomic tracing resolution. This alternation expanded the core genome (i.e., the cgSNP searching range) from 3.97 to 4.51 Mb, and the average number of pairwise cgSNPs among 4.3 isolates increased from 36 to 51, indicating a 41.7% increase in resolution (Fig. 4C). Despite the improvement, several of the international isolates in the preceding example still exhibited the identical cgSNP profile (Fig. 4D). Out of the nine UK isolates that resembled the Shanghai isolate, six were imported from Pakistan via international travel (25, 26), explaining their genomic similarity. However, the remaining three lacked information on whether they were imported and from which countries they originated, therefore, their origin in Pakistan cannot be fully confirmed.

Expanded examination to global 4.3 showed the pattern of <5 cgSNP distance for the isolates from different countries of the same continent was, in general, similar to that from different continents, suggesting intercontinental transmission was almost as common as international transmission (Fig. 4E). The most frequent international transmission appears to occur between the UK and Pakistan; the most frequent intercontinental transmission between Europe and Asia (Fig. 4F).

Phenotypic advantages of 4.3.1 over other lineages

To understand the advantage of 4.3.1 as a pandemic clone, we selected strains to represent *S*. Typhi clades of different genetic backgrounds from our Chinese collections and conducted a series of *in vitro* assays (Table S4). In general, the 4.3.1 isolates exhibited significantly better intercellular survival abilities than isolates from the primary clades 0, 2, and 3, within both the human myeloid leukemia cell line (U937) (Fig. 5A) and human monocytic leukemia cell line (THP-1) (Fig. 5B) at 12-h post-infection. Compared with a

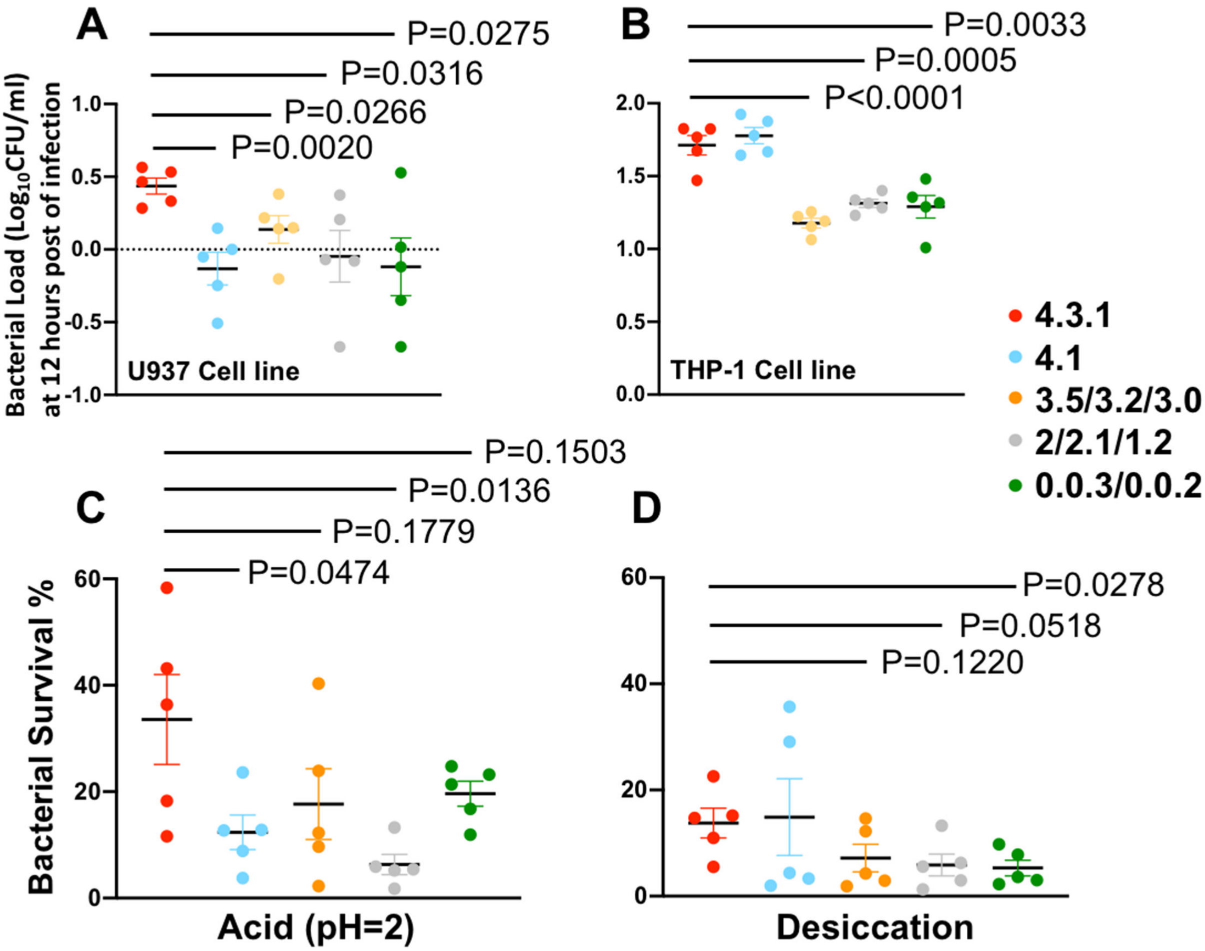

FIG 5 *In vitro* phenotypic comparison between 4.3.1 and other clades. Cellular invasion assays in the U937 cell line (A) and THP-1 cell line (B). The *y*-axis scale represents the $\log_{10}$ value of the ratio of detected bacteria at 12 h when compared with the initial bacteria that successfully invaded. *In vitro* tolerance assays with acid (pH = 2) (C) and desiccation (D). The *y*-axis scale represents the percentage of detected bacteria compared to the initial inoculation. Four groups of clinical isolates (Table S4) were chosen based on their lineage origin and availability in the current collection. The unpaired two-tailed *t* test was performed to assess the difference between groups with the calculated *P* value.

close relative 4.1, 4.3.1 also shows a better survival rate within U937 cells. Regarding tolerance to acid (Fig. 5C) and desiccation (Fig. 5D), we also observed that 4.3.1 isolates have better survival rates, even though the *P* value did not always reach the significant threshold. However, there are no dramatic differences in biofilm formation among lineages under the four examined conditions (Fig. S9). Interestingly, all the isolates show strong biofilm formation capabilities under swine bile salt medium with anaerobic conditions.

DISCUSSION

Here, we conducted, for the first time, a genomic epidemiology study of *S*. Typhi infection in China and found that both the “long-cycle” and “short-cycle” transmission modes commonly co-exist, providing striking regional heterogeneity. Most infections in eastern China resulted from “short-cycle” transmission, as revealed by their close match with international isolate genomes. This finding can be explained by the close connection of the populace in this region with other countries, such as southern Asia. By contrast, isolates from the other provinces displayed explicit geographical restrictions, suggesting that infections are attributable to the long-term circulation of the locally endemic clones. Dated phylogeny analysis further uncovered that endemic Chinese clones were not entirely indigenous but were, and continue to be, imported for several hundreds of years. For example, *S*. Typhi in northwestern China may well have been imported by frequent pilgrims from the Middle East, whereas the *S*. Typhi found in southern China almost certainly originated in adjacent Southeast Asia, a known reservoir for global typhoid fever (4). An interesting question is why *S*. Typhi imported to southern and northwestern China eventually developed into endemic clones, whereas those imported to eastern China only caused sporadic cases. Likewise, 4.3 imported by travelers to European countries has not created endemic disease, whereas importation to Africa via the same route, i.e., traveling public, has established a local dominant clone (27).

It has been recognized that climate and hydrological systems both play pivotal roles in the transmission of typhoid fever (2, 28–30). Northwestern and southern China are warm and damp, suitable for *Salmonella* growth. Furthermore, in the rural areas of these regions, local people utilize river or well water for cooking and cleaning (31, 32), similar to the endemic typhoid regions of South Asia, Southeast Asia, and Africa. As well as the popularity of foreign travel in eastern China, further multi-faceted contributions led to dual transmission modes in China. These may explain the relatively low correlation of typhoidal incidence with the GDP and tourist numbers (Fig. 1C).

In the era of the global village, genome-based epidemiology has been increasingly employed to reconstruct transmission links for many infectious diseases, which is built on the assumption that the natural origin of the disease tends to come from the region with the closest genome match (33, 34). This assumption has a premise that bacterial genomes must show robust geographical clustering, with considerable distance between isolates from different regions. This premise holds for most bacterial pathogens, including *S*. Typhi 2.1, 2.3, and 3.2 in China. By comparison, predicting the geographic origin of 4.3 genomes is much more challenging. The within-clade cgSNP distance is small, and frequent international transfer has distorted geographical clustering. Last but not least, the biased data sources of public databases have impeded global tracking investigations. Many of the developing countries, which are the real sources of typhoid disease, have submitted very few genomic data sets, probably due to the cost of establishing sequencing-based surveillance systems. Whereas the UK holds the largest data set of sequenced isolates, making it more likely to be the country with the closest genome match to any query isolates. Consequently, when the travel history of the UK patients is missing, the UK is easy to be misidentified as the country of origin.

As proposed here, three measures may help address the above issues. First, a hierarchical typing scheme, e.g., using a specific reference genome for 4.3.1 isolates, has been shown to increase the resolution. Second, tracing the exact source country should depend not only on the count of cgSNP distance but also on the topology of the dated phylogeny or even more complicated spatial-temporal modeling that comprises all the closely related isolates (24). Third, well-integrated databases are urgently required, which include not only the site of isolation/sequencing but also the site of infection (or rather the travel history). Last, increasing the density of isolate collection and genome sequencing from developing countries, including China, would effectively avoid sampling bias and help depict an accurate transmission route.

Over the last three decades, intercontinental transmission and circulation have been dominated by 4.3.1 or called H58. In line with this study, we found that the short-cycle international transmission in China was exclusively attributed to 4.3.1. MDR was once thought to drive the worldwide expansion of 4.3.1 (12, 35), but MDR is also present in other clades. Our bile resistance assay refuted the hypothesis that 4.3.1 has higher bile resistance benefiting persistence in the gallbladder in asymptomatic patients, which is in line with a previous report that *S*. Typhi carriage is not restricted to any particular genotype (36). Interestingly, we found an improved ability of 4.3.1 to resist a low pH environment, which might allow easier access to the intestine. We also found that 4.3.1 can better survive and replicate in macrophages. While this ability assists 4.3.1 to elude the host immune response, it might also benefit 4.3.1 living within amoebae in the environment. Similarly, the improved capability of desiccation tolerance may likely contribute to the environmental persistence of 4.3.1. Notably, 4.3.1 may acquire these capabilities in a stepwise manner. Our results showed that 4.3.1 has comparable desiccation tolerance and intracellular survival abilities in THP-1 compared to its close relative 4.1. But 4.3.1 performs better in acid tolerance and survival in U937, suggesting 4.3.1 has evolved the latter two capabilities after it diverged from 4.1. Nevertheless, all the examined results are based on Chinese clinical isolates, further investigations with an extensive diversified collection in the global community are highly warranted.

In conclusion, we provided the largest genomic data set from China for global surveillance and AMR assessment for one of the oldest killer diseases in the world. More importantly, our nationwide study revealed a novel dual-transmission mode with distinct regional features, which also correlated with the climate, and social-economic parameters of those regions in China. A notable historic "long-cycle," mainly endemic in inter-mainland China, is associated with the provinces that require improvements to hygiene, particularly water sanitation. Recent "short-cycle" transmission, mainly in more advanced socioeconomic areas in eastern China, is related to intensified global travel and linked with the MDR pandemic 4.3.1. Furthermore, we provided new biological evidence of tolerance capabilities that may favor typhoid transmission. The gained knowledge in this study would tailor the policy with precise interventions according to distinct transmission hotspots and modes in different regions.

MATERIALS AND METHODS

Data on *S*. Typhi incidence and correlation analysis

The annual incidence of *S*. Typhi infection was obtained from the Data Center of China Public Health Science (https://www.phsciencedata.cn/). The temperature data were retrieved from the website of the National Oceanic and Atmospheric Administration (www.noaa.gov). The precipitation data were recovered from the software WheatA (http://www.wheata.cn/). The latitude data were obtained from the Baidu Baike database (https://baike.baidu.com/), using the provincial capital city to represent the province. The GDP data were retrieved from the OuWei database (https://www.ovo.com.cn/). The tourism data were obtained from the Baidu Wenku database (https://baike.baidu.com/). All the collected data sets are in Table S1. The Spearman correlation between the *S*. Typhi incidence and the variables was calculated with R software v4.0.3.

Bacterial isolates and WGS

A total of 705 *S*. Typhi isolates were recovered between 1960 and 2020, originating from 17 provinces in China (Table S2). The isolates yielded from humans (*n* = 690) or water (*n* = 10). Human samples included blood (*n* = 616), feces (*n* = 36), marrow (*n* = 4), anal swab (*n* = 1), bile (*n* = 1), body fluid (*n* = 1), urine (*n* = 1), and unknown type (*n* = 30). Water samples included effluent (*n* = 6), pipe water (*n* = 3), and well water (*n* = 1). The sources for the remaining samples included environment (toilet, *n* = 2) and unknown source (*n* = 3).

Most of the isolates were collected by several major CDCs around the country, including Zhejiang CDC, Shanghai CDC, and Shandong CDC. The First Affiliated Hospital of Zhejiang University School of Medicine contributed to assembling the Bacterial Resistant Investigation Collaborative System collection, which collected bloodstream patients from 23 tertiary hospitals and 29 non-tertiary hospitals covering 18 provinces of mainland China. These organizations collected the isolates from subordinate local CDCs under an active routine surveillance program. Human samples were collected from patients with clinical diagnosis (*n* = 653), confirmed carrier cases (*n* = 1), and people with unknown status of infection (*n* = 36).

Total genomic DNA was extracted from the *S*. Typhi using the TIANamp genomic DNA extraction Kit (RT405, TIANGEN BIOTECH, China) and subjected to WGS using the Illumina HiSeq 2000 or HiSeq 2500 platforms (Illumina, San Diego, CA, USA) to generate 150 bp paired-end reads. *De novo* assembly of genome sequences was performed using SPAdes v3.12.0 (37). Serotyping was further confirmed by SeqSero2 v1.1.1 and SISTR v1.0.2 (38, 39).

Genotyping and phylogenetic analyses

To provide global context, a total of 5,190 publicly available *S*. Typhi genomes retrieved from the Enterobase *Salmonella* database and NCBI genome database (until 9 May 2021, including 26 genomes of Chinese isolates and 5,164 international isolates with the genomes) were included for analysis in addition to the genomes sequenced in this study (Tables S2 and S3). The cgSNPs were classified by mapping the assemblies of all query genomes to the reference sequence of *S*. Typhi strain CT18 (accession no: AL513382) with SNIPPY software v4.4.4 (40). The recombinant regions were removed using Gubbins v2.4.1, inset in SNIPPY (41). From the identified SNPs, a subset of 68 was assigned *S*. Typhi isolates to previously defined lineages according to the existing extended *S*. Typhi genotyping framework with GenoTyphi v1.9.1 (9). The genomes belonging to 4.3 were also mapped to the reference sequence of 4.3 strain ERL052042 (accession no: GCF_001088345) to obtain a second set of cgSNP using the same analytical procedures as the above and below methods.

Concatenated cgSNPs were aligned to build maximum likelihood (ML) phylogenetic trees using IQ-Tree v2.2.0 with default parameters (42). The ML trees were displayed and annotated using iTOL v6 (43). The population structure of the global *S*. Typhi collection was also analyzed by hierarchical Bayesian Analysis of Population Structure v6.0 (44), a phylogeny-free population genetics approach; six levels of clustering were performed in the hierarchy, and a prior upper boundary of 80 clusters was set.

Pairwise genetic distances (the difference in the number of cgSNPs) within and between SCs were calculated from the cgSNP alignment using the dist.dna function in the R package ape v5.4.1.

Temporal and phylogeographical analysis

To verify the temporal structure of the dominant four clades in China, we first used TempEst v1.5.1 to assess temporal structure by conducting a regression analysis of the root-to-tip branch distances of the ML tree as a function of sampling date (45). A date randomization test was also conducted by the TipDatingBeast v1.1 R package (46), in which 20 times of analysis were repeated (47). Then, the four clades were subjected to model-based most recent common ancestor dating and phylogeographical reconstruction using Bayesian evolutionary analysis by sampling trees (BEAST) v2.6.7 (48). To understand international transmission events, the representatives of international isolates were also included in this analysis. We identified clusters of closely related isolates with the same sample source, isolation year, and country of isolation and differed by less than five cgSNPs. One representative isolate was randomly selected from each cluster and was kept in the analysis.

The BEAST analysis was performed on alignments of concatenated cgSNPs following previously described procedures (11). Briefly, the GTR+Γ4 substitution model, Bayesian skyline model, and relaxed log-normal molecular clock were chosen; the chain length was 100 million, with sampling at every 10,000 iterations. Maximum clade credibility trees were generated using TreeAnnotator v2.6.7. Figtree v1.4.3 was used to annotate and visualize the tree. The effective population size was estimated by using Tracer v1.7.1.

Identification of AMR-associated determinants

ABRicate v0.8 and the CGE ResFinder database were used to investigate AMR-associated genes (49). Plasmid replicons were identified using ABRicate v0.8 and PlasmidFinder database (50). Point mutations in the quinolone-resistance determining region of genes *gyrA*, *gyrB*, and *parC*; and the *acrB*- mutations associated with azithromycin resistance were detected using ResFinder v4.1.0 and PointFinder database (49).

Rational choice of Chinese bacterial strains for *in vivo* assays

The strains used in this study are listed in Table S4. These strains were chosen to better reflect significant Chinese clades, with the purpose of comparative analysis for pandemic clone 4.3.1. Among three major primary clades (2, 3, and 4), two to three additional major genotypes of each primary clade were considered, including 2.1, 2, and 2.3.4 from primary clade 2, 3.2.1, 3.5, and 3.0.1 from primary clade 3, and 4.3.1 and 4.1 from primary clade 4. For other minor primary clades, two genotypes with clearly known classification names (0.0.3 and 0.0.2) were selected for primary clade 0, and we used the only available strain representing primary clade 1. For lineage 4.3.1, each of its three genotypes (4.3.1, 4.3.1.2, and 4.3.1.1P1) was highly linked to a geographical region of China: subtype 4.3.1 was mainly from Northwestern China (51/53, 96.2%), lineage 4.3.1.1 was mainly from Eastern China (6/6, 100%), and lineage 4.3.1.2 was mainly from Eastern China (5/5, 100%). Additionally, diversities of years of bacterial isolation and ages/sexes of corresponding patients were both fully considered for a better-represented isolate. Notably, our choice of strains is highly limited to our Chinese collection. The above strains were recovered and routinely grown in Luria Broth (LB) medium.

Acid stress assay

Overnight cultures of 26 strains were transferred to fresh LB medium at a ratio of 1:100 and cultured at 37°C, 220 r/min to OD_{600nm} 0.4–0.5 (10^9 CFU/mL). Plate-count (PC) method was used to record the initial bacterial concentration. Appropriate diluent (10 µL) of the original inoculum was streaked on an LB plate, and incubated at 37°C for 14–18 h (three replicates were performed for each sample). NaCl (Sinopharm Chemical Reagent Co., Ltd), NaOH, and HCl (AR, SCR/HuShi) were used to prepare physiological saline (pH = 2). A 10 µL resuspension solution mentioned above was 10× gradient diluted in physiological saline (pH = 2) to 10^7 CFU/mL and then placed at 37°C for 10 min. The plate counting method was used for recording the number of viable bacteria. The survival rate of the bacteria was calculated (the number of viable numbers/the number of initial bacteria × 100%). Data were analyzed using GraphPad Prism v9.0 software. The unpaired two-tailed *t* test was performed to assess the difference between groups.

Desiccation suppression assay

Overnight culture (16 h at 37°C 220 r/min) of 26 strains was prepared and adjusted to OD_{600nm} value 1.0 (10^9 CFU/mL). A total of 50 µL inoculum was added to a 96-well plate. And the plate was placed in a sealed box containing saturated potassium acetate (Sinopharm Chemical Reagent Co., Ltd) at 37°C for 24 h. After that, the plate counting method was performed (three replicates for each strain) to calculate the survival rate of the bacteria. The unpaired two-tailed *t* test was performed to assess the difference between groups.

Biofilm assay

Biofilm assay was performed in a similar way to our previously reported (51, 52). As mentioned in the desiccation suppression assay, overnight culturing was carried out in LB broth. Bacteria were transferred at a ratio of 1:100 into LB medium supplemented with Swine Bile Salt (0.5%), Ox Bile Salt (0.1%), and No.3 Bile Salt (0.1%), respectively. These bile salts were purchased in Shanghai Bo Microbiology Technology Co., Ltd. After thoroughly mixing, 200 µL inoculum was seeded in each 96-well plate in quintuplicate. *Escherichia coli* strain ATCC25922 and *P. aeruginosa* ATCC27853 were used as the positive control. The inoculated plate was incubated at 28°C for 24 h under aerobic and anaerobic conditions, respectively. After 24 h, the wells of the inoculated plate were washed gently with ddH_2O for three times. After drying, each well was stained with 200 µL of crystal violet (Sinopharm Chemical Reagent Co., Ltd) at room temperature for 20 min. After staining, each well was washed gently with ddH_2O for three times and 200 µL f 75% ethanol (Sinopharm Chemical Reagent Co., Ltd) was added. The dye was wholly dissolved and decolorized by shaking for 20 min. Before measuring results, the product of decolorization was transferred to a new microtiter plate. OD_{600nm} value of each stained well was measured using a microtiter-plate reader of the Tecan spectrophotometer. The unpaired two-tailed *t* test was performed to assess the difference between groups.

Intracellular survival assay

Cellular assays referred to methods previously reported (53, 54). RPMI1640 (Gibco) containing 5% fetal bovine serum (FBS; purchased from Biowest) was applied as a cell culture medium for recovering and culturing. Cells were grown in an incubator maintained at 37°C with 5% CO_2 and passaged to the fifth generation. The THP-1 cells were diluted to 5×10^4 cells/mL by RPMI1640 supplemented with 5% FBS and 50 ng/mL PMA for 48 h. U937 cells were diluted to 5×10^4 cells/mL by RPMI1640 supplemented with 5% FBS and 25 ng/mL PMA for 48 h to prepare the cell lines. The culture medium was discarded and replaced with RPMI1640 (containing 5% FBS) for an additional 12 h culture.

The intracellular survival assay was performed as follows: (i) the overnight culturing was carried out in LB broth as mentioned in the desiccation suppression assay; (ii) the inoculum was diluted with RPMI1640, and a volume of 200 µL was transferred to the well for infecting cells with an MOI of 50:1 for 1 h at 37°C, while plate counting method was performed for recording concentration of initial bacteria in the inoculum; (iii) the cells were washed three times with warm RPMI1640 to remove extracellular bacteria; (4) gentamicin was added to the RPMI1640 medium (containing 5% FBS) at a final concentration of 100 µg/mL and the culture was incubated for 1 h to kill extracellular bacteria; (5) RPMI1640 medium (containing 5% FBS) supplemented with 10 g/mL gentamicin (Sangon Biotech) was used for the new culture after discarding the old medium, and the new culture was incubated at 37°C with 5% CO_2 for 0 and 12 h, respectively, while the cell lysis were subjected to plate couting at each time point; and (6) the survival rate of the bacteria was calculated (the number of viable bacteria at 12 h/the number of initial bacteria that successfully invaded at 0 h × 100%). The unpaired two-tailed t test was performed to assess the difference between groups.

The characterization of the molecular mechanisms whereby our brain codes, stores and retrieves memories remains a fundamental puzzle in neuroscience. Despite the knowledge that memory storage involves gene induction, the identification and characterization of the effector genes has remained elusive. The completion of the Human Genome Project and a variety of new technologies are revolutionizing the way these mechanisms can be explored. This review will examine how a genomic approach can be used to dissect and analyze the complex dynamic interactions involved in gene regulation during learning and memory. This innovative approach is providing information on a new class of genes associated with learning and memory in health and disease and is elucidating new molecular targets and pathways whose pharmacological modulation may allow new therapeutic approaches for improving cognition.

Keywords: Behavior, genomics, learning, memory, microarray

Received 15 February 2005, revised 29 April 2005, accepted for publication 29 April 2005

One of the most ambitious goals of modern neuroscience is to identify the mechanisms whereby our brain codes, stores and retrieves memories. Two general forms of memory can be classified by their duration: short-term memory (STM), which is rapidly formed and can outlast training for minutes or hours, and long-term memory (LTM), which lasts from hours to days, weeks or even years. STM involves post-translational modifications of preexisting molecules that alters the efficiency of synaptic transmission. In contrast, LTM can be blocked by inhibitors of transcription or translation indicating that it is dependent on *de novo* gene expression (Davis & Squire 1984; Stork & Welzl 1999). Proteins newly synthesized during memory consolidation may contribute to restructuring processes at the synapse and thereby alter the efficiency of synaptic transmission beyond the duration of STM. Revealing the dependence of LTM on protein synthesis, however, provides no information about the identity and specificity of the required proteins.

Because the quantity of a particular protein is often reflected by the abundance of its mRNA, a variety of methods has been used to describe only a limited number of differentially expressed genes during LTM (Stork & Welzl 1999). Successive screening therefore were needed to uncover how many and which genes are involved in memory and how do they interact functionally to effect memory storage. To survey the gene-based molecular mechanisms that underlie LTM, genome-wide expression analysis is being used in a variety of behavioral conditions (Cavallaro *et al.* 2001; Cavallaro *et al.* 2002; D'Agata & Cavallaro 2003; Dubnau *et al.* 2003; Leil *et al.* 2003; Luo *et al.* 2001; Rampon *et al.* 2000). This genomic approach requires the development of various laboratory protocols, as well as the development of database and software tools for efficient data collection and analysis. A basic understanding of these computational tools is therefore required for optimal experimental design and meaningful data analysis. For this reason, in the present review, we will outline the main procedures of microarray analysis (Fig. 1) before describing its application in the learning and memory field. For a more general description of microarray technology, the reader is referred to other reviews (Heller 2002; Hess *et al.* 2001; Noordewier & Warren 2001; Quackenbush 2001).

Expression profiling by DNA microarray technology

Basic principles

A DNA microarray is a grid of DNA spots, called probes, each containing a unique DNA sequence (Fig. 2). Spots contain either DNA oligomers or a longer DNA sequence designed to be complementary to a particular mRNA of interest. When a microarray is hybridized to fluorescence-tagged complementary DNAs or RNAs derived from messenger or total RNA, each spot is a target for the mRNA encoded by a gene. A laser can then excite the bound cDNAs or cRNAs and a scanner collects fluorescence intensities from each spot on the slide. The intensity of the fluorescence at each array element is proportional to the expression level of that gene in the sample. The choice of having oligomers or longer

Self-organizing maps (SOM)
Functional clustering
Follow-up studies
Confirmatory studies (RT-PCR, immunohistochemistry, western blot analysis)
Genetic modulation (knock-out, knock-down or overexpression)
Pharmacological modulation

Figure 1: Experimental design, data analysis and follow-up experiments in DNA microarray experiments. DNA microarray is a very powerful technology, but it can be useless if the experimental design is not properly identified and executed with precision and accuracy. Because of variability across different samples, it is important to perform microarray experiments on replicate samples. These replicates can be either 'technical', where the same sample pair is repeated, or 'biological', where the experiment is repeated and an equivalent sample used. Sophisticated computational tools are then needed for the management and analysis of data that result from these experiments. Microarray data are commonly normalized to correct differences in intensity levels. Once normalized, a series of restrictions (gene filtering) can be applied to the data obtained. These restrictions include factors such as quality control, expression level constraints, sample-to-sample fold comparison and statistical group comparisons. More complex computational methods are needed to investigate and interpret microarray data and to group genes based on their expression levels or gene ontologies. Follow-up experiments can finally be used to confirm/modulate the expression/activity of candidate genes or their encoded proteins.

cDNA sequences yields two different microarray technologies: oligonucleotide and cDNA microarrays, respectively. The thing that makes microarrays the most promising technology for genome-wide expression analysis is the number of DNA probes that it is possible to place on a microarray. Already there are microarrays with probes for every gene in yeast, and others with over 40 000 human genes. This allows researchers to observe the response of whole genomes to various stimuli instead of one gene at a time.

Computational analysis of microarray data

Microarray analysis results in large amounts of data that are difficult to interpret without computational methods. The simplest analysis involves two samples, representing a test condition and a control condition and yields a list of paired expression values, one pair for each gene. As illustrated in Fig. 2, these pairs can be represented graphically by a scatter plot, with the values of sample one plotted on the x-axis and the values of sample two plotted on the y-axis. The resulting correlation plot provides a visual image of the relationship between the two expression profiles. In this plot, genes with similar expression levels in the two samples should have points on the identity line ($y = x$), and genes that are expressed differentially lie at some distance from this line. However, the problem is that microarrays do not measure expression levels directly, but rather intensity levels, as represented by the amount of phosphorescent dye that was recorded by a scanner. Many other factors, such as the overall mRNA concentration of the two samples, the saturation

1601183x, 2006, 3, Downloaded from https://onlinelibrary.wiley.com/doi/10.1111/j.1601-183X.2005.00159.x, Wiley Online Library on [13/10/2025]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

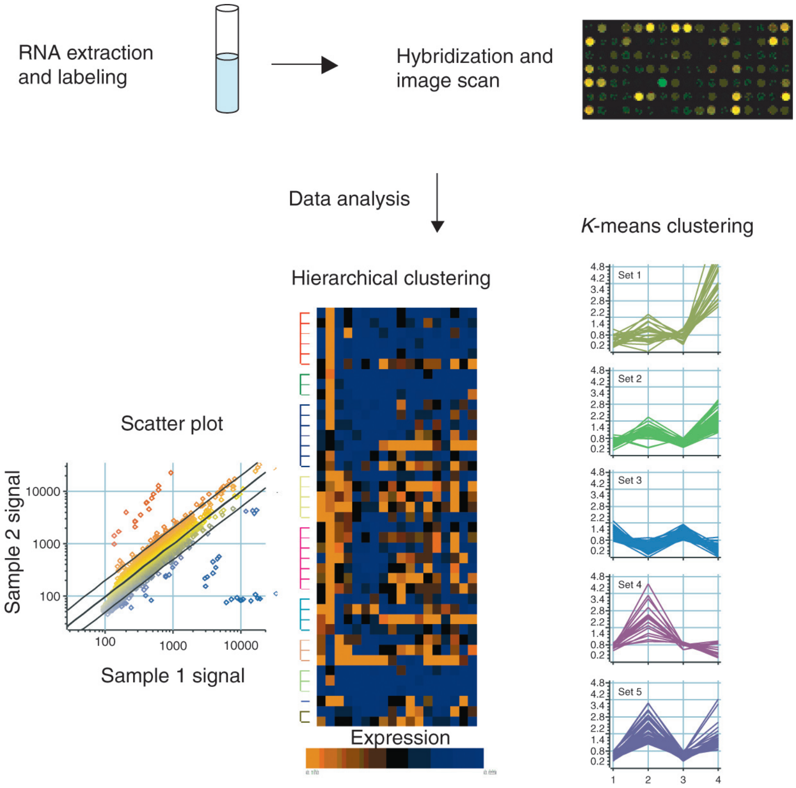

Figure 2: DNA microarray methodology. Total or messenger RNA is extracted, reverse transcribed, labeled with different fluorochromes (e.g. Cy3 and Cy5) and hybridized to microarrays. At the end of the hybridization, a laser scanner collects the image produced by the dye. Intensity values from each spot are calculated and then analyzed by specific software. Data can be represented graphically by a scatter plot, with the values of sample one plotted on the *x*-axis and the values of sample two plotted on the *y*-axis. Data obtained under different conditions (e.g. different time points) can be analyzed with different algorithms such as hierarchical or *k*-mean clustering.

effects in the hybridization or the quenching effect of the phosphorescent dyes can affect these intensity values. In order to correct these differences in intensity levels, the raw data can be normalized, for example, by using a normalization constant derived from housekeeping or spiked control genes.

Once normalized, a series of restrictions (or filters) can be applied to the data obtained. These restrictions include factors such as quality control, expression level constraints, sample-to-sample fold comparison and statistical group comparisons. The simplest way to identify interesting genes in DNA-microarray experiments is to search for those that are consistently either up- or downregulated. Relative differences in expression levels (fold changes) have been typically employed in group comparisons of gene expression. This approach, however, is somewhat arbitrary and inherently subject to high error rates because information on sample variance is not exploited. If array experiments are replicated to an extent that permits direct estimates of the variance of each individual transcript, parametric or non-parametric statistics can be applied. In these cases, however, a high number of false-positive results are expected by chance when one relies on the nominal *P*-value. For instance, when testing 10 000 transcripts we would expect to misidentify about 500 genes as significant ($P < 0.05$), even when there is no real difference in gene expression. Multiple testing corrections therefore are needed to adjust the individual *P*-value to account for this effect.

More complex computational methods are needed to monitor several gene expression profiles, such as those arising from time-course studies, and various clustering techniques have been applied to the identification of patterns in gene-expression data. Cluster analysis is a commonly used method to investigate and interpret gene expression data sets. By grouping together genes that have similar expression profiles, cluster analysis can be used for extraction of regulatory motifs, inference of functional annotation and classification of cell types or tissue samples.

Cluster analysis

The term *clustering* stands for a method that makes it possible to partition a set of objects (genes) into subgroups with similar features called clusters. These partitions have to satisfy the following features: *Homogeneity* in the cluster (the objects which belong to the same cluster have to be as similar as possible) and *Heterogeneity* among clusters (the objects which belong to different clusters have to be as different as possible).

A clustering method generally consists of two distinct components: a distance measure (or similarity coefficient) that indicates how similar two gene expression patterns are (or more generally, two clusters), and a clustering algorithm, which sorts the data and groups genes together on the basis of their separation in expression space.

Measure of distance or similarity coefficient

Many of the advanced analysis techniques are based upon measures of gene similarity. Similarity between genes is

1601183x, 2006, 3, Downloaded from https://onlinelibrary.wiley.com/doi/10.1111/j.1601-183X.2005.00159.x, Wiley Online Library on [13/10/2025]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

usually based on the correlation between the expression profiles of the genes. For expression data, we can solve the problem of 'similarity' mathematically by defining an 'expression vector' for each gene that represents its location in 'expression space'. In this way, expression data can be represented in *n*-dimensional expression space, where *n* is the number of experiments and where each gene-expression vector is represented as a single point in that data space.

In any clustering algorithm, the calculation of a 'distance' between any two objects is fundamental for placing them into groups. There are various methods for measuring distance, typically falling into two general classes: metric and semimetric (or similarity coefficient). Each of these takes two expression patterns and produces a number representing how similar the two genes are.

Detailed mathematical description of distance metrics used in clustering analysis can be retrieved in other reviews (Quackenbush 2001). The most common metric distance is the Euclidean distance. It simply is the geometric distance in the multidimensional space. The most commonly used semimetric distance measure in the analysis of gene expression data is the Pearson's correlation coefficient *r*.

Clustering algorithms

After providing means of measuring distance between genes, clustering algorithms sort the data and group genes together on the basis of their separation in expression space. Various clustering techniques have been applied to the identification of patterns in gene-expression data. Most cluster analysis techniques are hierarchical, the resultant classification has an increasing number of nested classes and the result resembles a phylogenetic classification. Non-hierarchical clustering techniques also exist, such as *k*-means clustering, which simply partition objects into different clusters without trying to specify the relationship between individual elements. Examples of hierarchical and *k*-means clustering are reproduced in Fig. 2.

Although cluster analysis techniques are extremely powerful, great care must be taken in applying this family of techniques. Eventhough the methods used are objective in the sense that the algorithms are well defined and reproducible, they are still subjective in the sense that selecting different algorithms, different normalizations, or different distance metrics, will place different objects into different clusters. Furthermore, clustering unrelated data would still produce clusters, although they might not be biologically meaningful.

Numerical, semantic and mixed clustering. Cluster analysis is a methodology to identify groups of genes that share common expression characteristics and behaviors. It has been frequently exploited in the analysis of genome-wide expression data, as the experimental observation that a set of genes is coexpressed implies that the genes share a biological function and are under common regulatory control.

Frequently, the clustering is used to group together genes considering only similar expression profiles, but it does not consider other well-known features of the gene properties. Actually, genes with a different profile expression could have similar functions as well and the classical clustering methodologies do not put it in evidence.

In order to extract knowledge from gene expression information, cluster analysis can be organized in three different approaches: numerical, semantic and mixed clustering.

The *numerical clustering* method is applied to the levels of gene expression. It tends grouping genes with a similar expression profile in the same clusters and makes sure that genes having different profiles with similar semantic features fall in different clusters. These considerations suggest that simple numerical clustering algorithms are inadequate to infer the genes' and proteins' role.

In order to discover more complex relationships among gene sequences the *semantic clustering* is used. The term *semantic clustering* indicates methods of clustering based on semantic characteristics, such as gene ontologies. When categorical domains are ordered, they can be turned in numerical values in order to transform those that are similar in near values. After that, methods of classical numerical clustering can be applied to that data set. When categorical domains are not ordered, however, this approach does not necessarily produce meaningful results. In this case, the k-modes algorithm can be used to remove this limitation.

Finally, more useful analyses can be performed using the *mixed* clustering. In this case, each gene can be represented from a vector in the n + m-dimensional space, where n is the number of levels of gene expression and m is the number of semantic features transformed in numerical values. Then, each gene-expression-semantic vector is represented as a single point in data space and any measure of distance can be adopted to calculate the distance between any two genes. The *mixed* clustering tends to group genes with similar expression profiles as well as genes with similar semantic features.

In order to perform *semantic* and *mixed* clustering we have developed new informatics applications (Fig. 3). Functional information is automatically retrieved by means of the software application GENELINK (Fig. 3A). This application is designed to retrieve genomics and proteomics information from external worldwide databases (NCBI GenBank and LocusLink). Before performing the semantic clustering, the functional annotations have to be turned into numerical values to transform features that are similar functionally in near values. For each gene ontology (GO) number, for example, the software application GENE ONTOLOGY SYSTEM (GOS) assigns a new GO number in order to identify the hierarchical relationships among GOs (Fig. 3b). The basic idea is that two related GOs must be coded with two closest GO numbers. After this renumbering process, methods of classical numerical clustering can be applied to the original data set (Fig. 3c) to perform numerical (Fig. 3d), semantic (Fig. 3e), or mixed (Fig. 3f) clustering. In this way, cluster analysis can effectively extract functional information from gene expression data.

1601183x, 2006, 3, Downloaded from https://onlinelibrary.wiley.com/doi/10.1111/j.1601-183X.2005.00159.x, Wiley Online Library on [13/10/2025]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

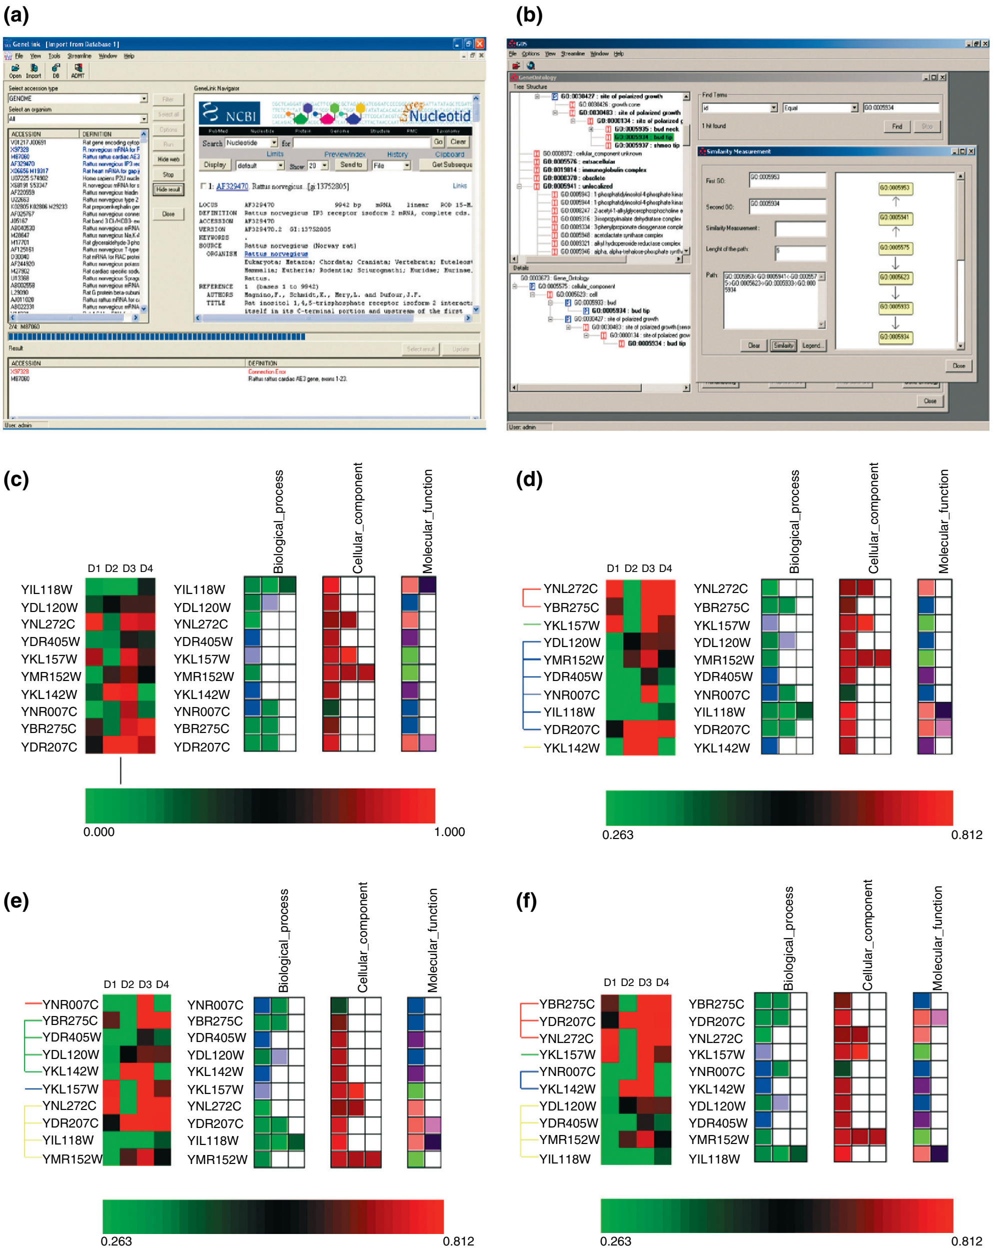

Figure 3: Numerical, semantic and mixed clustering. This term indicates a method of clustering genes based on their semantic characteristics. In this figure, gene ontologies (GOs) terms are used as examples of semantic features. Currently, three independent ontologies' information are accessible on the World Wide Web (http://www.geneontology.org): biological process (GO1), molecular function (GO2) and cellular component (GO3). We have developed an informatics application that we call GENELINK that is capable to automatically retrieve functional annotations from external databases (NCBI GenBank and LocusLink) (panel a). Before performing the semantic clustering these functional annotations have to be turned in numerical values in order to transform features that are similar functionally in near values. For each GO number, the software application GENE ONTOLOGY SYSTEM (GOS) assigns a new number according to a depth visit of the tree that represents the hierarchical relationships among GOs (Panel b). After this renumbering process, methods of classical numerical clustering can be applied to the normalized data set. Panels c–f show a gene expression matrix (left) and a GO map (right). The GO map is composed of three grids, one for each type of gene ontology: biological process, cellular component and molecular function. Each element of a grid is colored on the basis of the GO number obtained by GO renumbering. (some genes have more than one GO). Panel c represents unclustered gene expression data of 10 genes in four different conditions together with their GO map. Panel d shows clustered gene expression data of the 10 genes in four different conditions (GOs are not grouped). In panel e, gene ontologies are clustered (gene expression data are not grouped). Panel f shows a mixed (gene expression and GO data together) clustering (balanced clusters on both the universes can be seen).

The use of a genomic approach for studying learning and memory

The following part of this review will focus on the use of a genomic approach to dissect and analyze gene-based mechanisms underlying learning and memory. We will highlight gene expression microarray analysis performed in different behavioral paradigms (eye-blink conditioning, water- and T-maze learning and passive avoidance conditioning). For space limitation, in this review we will try to give a broad view of the results obtained refraining from discussing each of the genes implicated by microarray analysis.

Eye-blink conditioning

To begin a comprehensive survey of the molecular mechanisms that underlie LTM, we used cDNA microarray technology to perform genome-wide expression analysis after classical conditioning of the rabbit's nictitating membrane response (NMR), a uniquely well-controlled associative learning paradigm (Fig. 4a) (Cavallaro *et al.* 2001). Classical conditioning of the rabbit NMR involves the presentation of an innocuous stimulus such as a tone followed by a noxious stimulus such as air puff to or electrical stimulation around the eye (Gormezano *et al.* 1962). Extensive lesion and recording data have implicated the cortex of the cerebellum and in particular, lobule HVI, in classical conditioning of the rabbit NMR (Berthier & Moore 1986; Gould & Steinmetz 1996; Gruart & Yeo 1995; Schreurs *et al.* 1991; Yeo *et al.* 1985). Although the hippocampus may not be necessary for NMR conditioning, recording data do show consistent eye blink-conditioning-specific hippocampal changes (Coulter *et al.* 1989; Sanchez-Andres & Alkon 1991). In addition, imaging studies have implicated both structures in human eye blink conditioning (Blaxton *et al.* 1996; Logan & Grafton 1995; Molchan *et al.* 1994; Schreurs *et al.* 1997).

Messenger RNA levels from cerebellar lobule HVI and hippocampus of unpaired and paired rabbits were simultaneously analyzed with high-density cDNA microarrays containing more than 8700 cDNAs (Cavallaro *et al.* 2001). When gene expression patterns were compared, mRNA levels of 79 and 17 genes differed more than twofold in lobule HVI and hippocampus, respectively (Figs 4b,c). These genes were operationally defined as 'memory related genes' (MRGs). Approximately 50% of the MRGs differentially expressed in the hippocampus were also differentially expressed in the HVI lobule, suggesting common mechanisms of memory storage in the two areas.

A majority of MRGs were downregulated, whereas only two genes that differed by a factor greater than 2 were upregulated in lobule HVI of paired animals (Fig. 4b). Because LTM can be blocked by transcription and protein synthesis inhibitors, most previous reports have focused on the identification of proteins whose expression is upregulated (Davis & Squire 1984). The preponderant reduction of gene expression during LTM therefore would not have been predicted and provides new and unexpected insights into the molecular mechanisms that underlie it. The specific role of the downregulation of MRGs following learning remains a matter of speculation. Downregulation of a gene may be the end point in a dynamic gene expression process that begins with upregulation during acquisition of the learned response. Alternatively, memory storage may require a balance of upregulation of some genes and downregulation of genes that exert inhibitory constraints on memory formation (Alberini *et al.* 1994). These latter genes might be termed memory suppressor genes (Abel & Kandel 1998).

A majority of the MRGs implicated have no currently recognized function and are not yet named. Complete nucleotide sequence determination, conceptual translation, expression monitoring and biochemical analysis are currently underway (D'Agata *et al.* 2003) and should provide a detailed functional understanding of these genes. Seventeen genes have significant similarity to known genes and can be grouped into different functional classes (Fig. 4D).

Our microarray analysis of eye blink-conditioned rabbits (Cavallaro *et al.* 2001) was the first reported in the literature to demonstrate the feasibility and utility of a cDNA microarray system as a means of dissecting the molecular mechanisms of associative memory. Further studies, however, were required at different time points and behavioral conditions to better understand the role of the implicated genes. To perform such studies we and others have moved to rat or mice, two animal species that are better suitable for genomic studies than rabbit in terms of sequenced genes and available microarrays.

T-Maze learning

Microarrays have been used to analyze hippocampal gene expression in rats following training in a multiunit T-maze (Luo *et al.* 2001). In this study, the expression of 28 genes (18 known genes and 10 ESTs) was found to be increased in maze-trained animals compared with yoked control rats that were trained in a straight runway. Some of the known genes are involved in Ca^{2+} signaling, Ras activation, kinase cascades and extracellular matrix function. None of them, however, overlap with genes identified by microarray analysis in the other experimental paradigms examined in this review. Although the aversive foot shock was applied in equal duration and frequency to both the trained and control rats, changes in gene expression could be ascribed to other differences among the two groups, such as locomotor activity. In addition, because the animals were pretrained on day 1 and T-maze-trained on days 2 and 3, the time-dependent patterns of gene regulation during acquisition and consolidation of memory are unknown.

Water-maze learning

To detect learning related changes, microarray analysis has been used by two laboratories to characterize gene expression profiles in animals trained in the Morris water maze (Cavallaro *et al.* 2002; Leil *et al.* 2002; Leil *et al.* 2003). In this learning paradigm, a rodent learns to locate a submerged island in a large pool by

Figure 4: Microarray analyses of eye blink conditioned rabbits. (a) Mean percent conditioned responses in paired, unpaired and sit-control rabbits as a function of three training sessions. To relate changes in gene expression to a learning task, we used pairings of a tone and periorbital electrical stimulation in a standard delay-conditioning procedure, training rabbits to asymptotic levels of conditioning over 3 consecutive days. Paired rabbits ($n = 12$) acquired conditioned responses to the tone and reached a mean terminal level of 94.7% conditioned responses, whereas the unpaired control rabbits ($n = 12$) responded to the tone at mean levels of less than 1.3% across the 3 days of stimulus presentations and sit-control rabbits ($n = 5$) had spontaneous blink rates of less than 1% ($P < 0.001$). Without further training or testing rabbits show a level of 80% conditioned responses as long as 1 month after the 3 days of the stimulus pairings used in the present experiments. Consequently, harvesting cerebellar and hippocampal tissue 24 h after 3 days of pairings ensured that rabbits were still at an asymptotic level of conditioning. (b–c) Scatter plot of gene expression levels for paired and unpaired animals in (b) cerebellar lobule HVI and (c) hippocampus. Messenger RNA levels from cerebellar lobule HVI and hippocampus of unpaired and paired rabbits ($n = 7$ per group) were simultaneously analyzed with high-density cDNA microarrays containing more than 8700 cDNA mouse clones with a length of 500–5000 bp and with averages in the 1-kb region. The estimated percentage of homology between mouse clones and rabbit genes is 88.98 ± 3.7 (mean ± SD). The cross species similarity and a complete list of the differentially expressed genes are available online at http://web.tiscali.it/sebastiano_cavallaro. (D) Differentially expressed genes with a known function are ordered into functional groups.

creating a spatial map using extra-pool cues. Leil *et al.* (2002) used cDNA-microarrays containing approximately 9000 clones to detect hippocampal gene expression changes between F1 hybrid mouse strains that perform well on the Morris water maze and inbred strains that perform poorly. Although this study was performed in a brain region intimately involved in spatial learning, genes differentially expressed in mouse strains may subserve other behavioral processes or functions. Indeed, in a later study, the same authors (Leil *et al.* 2003) used microarray analysis to characterize the differential expression of genes ($n = 3$) in the hippocampus of F1 hybrid mice after 2 days of water-maze training. Although mouse strains used were the same, no overlap was found between the genes revealed in the two studies. In addition, no overlap was found between genes differentially expressed in water-maze training (Leil *et al.* 2003) and those performed in the other behavioral paradigms examined in this review. This is probably due to a number of factors, including different genes on the arrays, different species or strains employed, brain regions and time point studied. In addition, because mice are very reactive to placement in

Figure 5: Water-maze learning. (a) Escape latencies of rats swimming to a submerged platform in the water maze during four consecutive trials. In order to reduce stress in the experimental day, the first day was dedicated to swimming training in the absence of an island. Each rat was placed in the pool for 2 min and was returned to its home cage. In the next day, half of the rats were placed again in the pool for a 2.5-min swimming session and were used as swimming controls. The other half were given four consecutive trials to locate the platform, each trial lasting up to 2 min. Rats were required to spend 30 seconds of an intertrial interval on the platform. The rats' escape latency was measured using a HVS2020 video tracking system (HVS Image Ltd, Hampton, UK). (b) Probe trial. To verify that the trained rats in fact learned the spatial location of the island, a group of six rats was trained to find the island and tested 24 h later on a quadrant analysis test. The trained rats swam significantly longer in the quadrant (red) where the island was located. (c–e) Venn diagrams of differentially expressed hippocampal genes. Hippocampal gene expression profiles in naïve, SC and water-maze trained rats were measured using microarrays containing 1263 genes relevant to neurobiology (Affymetrix GeneChip Rat Neurobiology U34 array). Genes differentially expressed in naïve and swimming control animals 1, 6 and 24 h after training were operationally defined as 'physical activity related genes' (PARGs), whereas genes differentially expressed in water-maze-trained animals compared with swimming controls were operationally defined as 'memory related genes' (MRGs) (c). Among these, 55 genes were upregulated (d), whereas 91 genes were downregulated (e) in at least one of three time points examined. (f) Hierarchical clustering of MRGs. A hierarchical clustering algorithm (Pearson correlation, separation ratio 0.5, minimum distance 0.001) was used to order MRGs in a dendrogram in which the pattern and length of the branches reflects the relatedness of the samples. Data are presented in a matrix format: each row represents a single gene and each column an experimental condition. The averaged normalized intensity from two replicates is represented by the color of the corresponding cell in the matrix. Blue, yellow and red cells, respectively, represent transcript levels below, equal or above the median abundance across all conditions. Color intensity reflects the magnitude of the deviation from the median (see scale at the bottom). A complete list of the differentially expressed genes is available online at http://web.tiscali.it/sebastiano_cavallaro.

water, gene expression differences may be due to stress responses rather than learning and memory.

To analyze the time-dependent patterns of gene regulation during water-maze training, we measured hippocampal gene expression profiles in naïve, swimming control and water-maze trained rats (Fig. 5a,b), using microarrays containing more than 1200 genes relevant to neurobiology (Cavallaro *et al*. 2002). When gene expression profiles in naïve and swimming control animals 1, 6 and 24 h after swimming sessions were compared, 345 genes were found differentially expressed more than twofold in at least two of the four conditions (Fig. 5c). These genes, operationally defined as 'physical activity related genes' (PARGs) indicate that physical activity and mild stress associated with behavioral training has a significant impact on hippocampal gene expression.

When gene expression levels in swimming control animals were compared with water-maze trained animals 1, 6, or 24 h after training, 140 MRGs were found (Fig. 5c). The majority of these MRGs (110 of 140) were also PARGs, i.e. influenced by physical activity. Among MRGs, 55 genes were upregulated in the hippocampus of water-maze-trained animals, whereas 91 genes were downregulated (Figs 5d,e).

Most of the MRGs, those differentially expressed between the swimming and spatial learning animal groups, were also affected during swimming alone but with entirely different temporal patterns of expression (Fig. 5f). Although learning and physical activity involve common groups of genes, the behavior of learning and memory can be distinguished from unique patterns of gene expression across time.

All of the MRGs identified during water-maze learning have a recognized function and can be classified into six major groups based on their translated product: (i) cell signaling (ii) synaptic proteins (iii) cell–cell interaction and cytoskeletal proteins (iv) apoptosis (v) enzymes and (vi) transcription or translation regulation. Some of these genes have been previously related to synaptic plasticity, memory, or cognitive disorders. For a complete description of the MRGs implicated by microarray technology, the reader is referred to our previous study (Cavallaro *et al*. 2002). In the following paragraph we will discuss only one of the MRGs, FGF-18, which has been further tested for its memory regulatory function.

FGF-18 is a novel member of the FGF family, which was shown to stimulate neurite outgrowth (Ohbayashi *et al*. 1998). Although the function of this peptide is still unknown, the

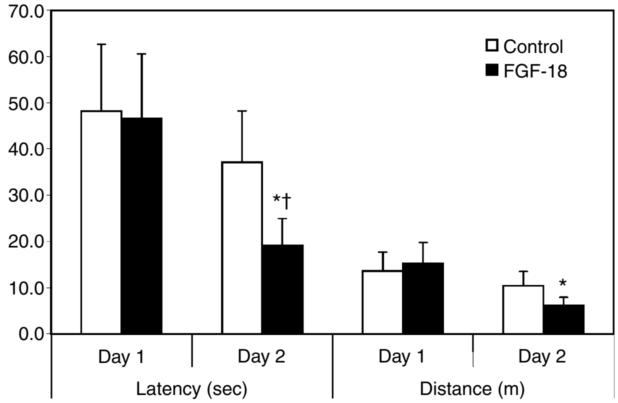

Figure 6: Effects of a single exogenous administration of FGF-18 on water-maze learning. Thirteen male Wistar rats (250–300 g) were implanted strereotaxically with stainless steel guide cannulae in the right and left lateral ventricles. On day 1, 1 week after surgery, animals were subjected to a 2-min swimming training session. Then, a water-maze training session was performed on days 2 and 3 and consisted in finding a submerged platform to escape from the water. Two trials were given to the animal for each session. The escape latency and distance to find the platform were monitored as described above. Ten minutes after the second trial on day 2, an intracerebroventricular administration of drug or vehicle was performed in both lateral ventricles. Six animals received 0.94 pmoles of FGF-18 and the other seven received a control injection of vehicle (saline). *day 1 vs. day 2, $P < 0.05$; †control vs. FGF-18, $P < 0.05$.

1601183x, 2006, 3, Downloaded from https://onlinelibrary.wiley.com/doi/10.1111/j.1601-183X.2005.00159.x, Wiley Online Library on [13/10/2025]. other members of its family are important signaling molecules in several inductive and patterning processes and act as brain organizer-derived signals during formation of the early vertebrate nervous system. Water-maze training but not physical activity induced the expression of FGF-18. To explore the effect of FGF-18 in spatial learning, we tested the effects of a single exogenous dose of FGF-18. Rats were trained in a Morris water maze for two trials and then injected intracerebroventricularly with 0.94 pmoles of FGF-18 or vehicle. As shown in Fig. 6, FGF-18 treatment improved spatial learning behavior by inducing a 49% reduction in the escape latency but no significant changes in motor activity.

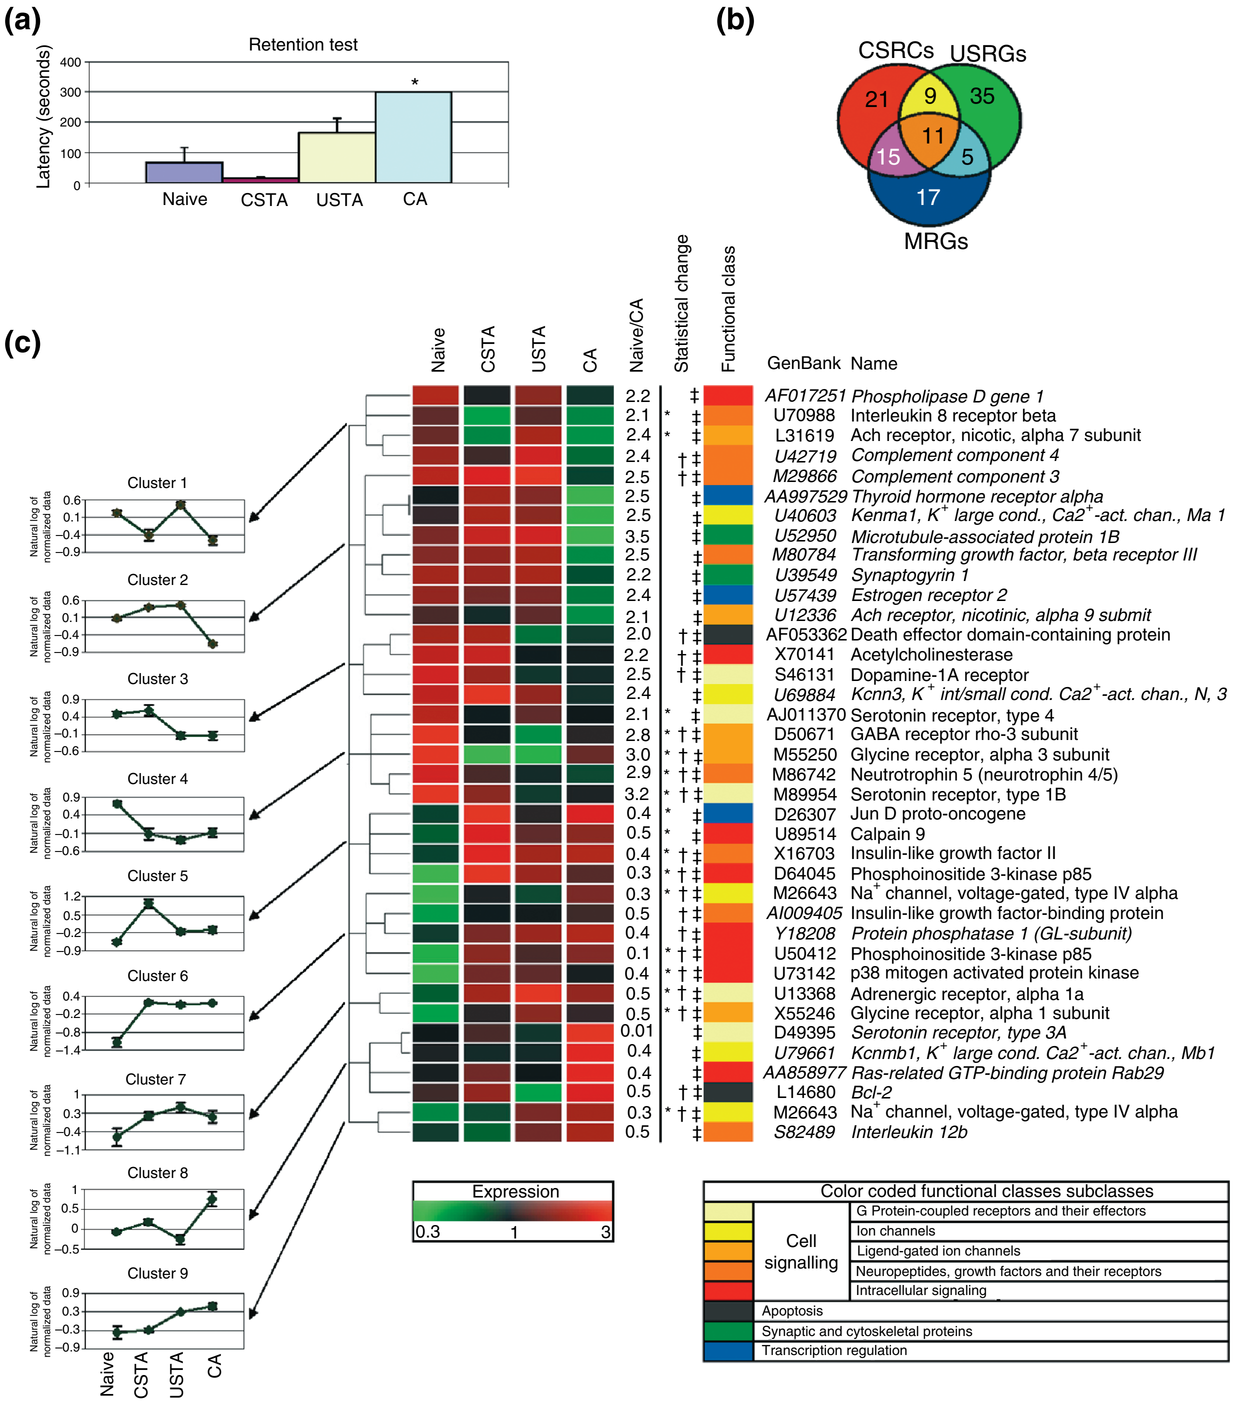
The data obtained in the hippocampus of water-maze-trained rats (Cavallaro *et al.* 2002) represent the first



1601183x, 2006, 3, Downloaded from https://onlinelibrary.wiley.com/doi/10.1111/j.1601-183X.2005.00159.x, Wiley Online Library on [13/10/2025]. Figure 7: Passive avoidance learning. (a) Passive avoidance retention test. Conditioned animals (CA) were trained to avoid moving from the lighted to the darkened section of a conditioning chamber by delivering a foot shock when they entered the darkened section. Control rats included untrained (naïve) animals, and animals exposed to the conditioned (CSTA) or the unconditioned (USTA) stimulus. Twenty-four hours after the training trial, half of the animals ($n = 4$ per group) performed the retention test to verify that the trained rats in fact learned the passive avoidance task. The animals were placed in the safe compartment with the door closed. After 2 min of acclimation the light turn-on, the door opened and the animal was allowed to enter the dark compartment. The latency to enter the dark compartment was recorded and used as the measure of retention. The rats avoiding the dark compartment for over 300 seconds were considered to have a memory of the training experience. During the retention trial, CA had a longer mean step-through latency than naïve, CSTA and USTA (*$P < 0.001$). (b) Venn diagrams of differentially expressed hippocampal genes. Hippocampal gene expression profiles in CA, USTA, CSTA and naïve animals were measured 6 h after training using microarrays containing 1263 genes relevant to neurobiology (Affymetrix GeneChip Rat Neurobiology U34 array). Genes differentially expressed between naïve and CSTA were defined as 'conditioned stimulus related genes' (CSRGs); genes differentially expressed between naïve and USTA were defined as 'unconditioned stimulus related genes' (USRGs); genes differentially expressed between naïve and CA were defined as 'memory related genes' (MRGs). (c) Hierarchical clustering of MRGs. A hierarchical clustering algorithm (Pearson correlation, separation ratio 0.2, minimum distance 0.001) was used to order MRGs in a dendrogram in which the pattern and length of the branches reflects the relatedness of the samples. Data are presented in a matrix format: each row represents a single gene and each column an experimental condition. The averaged normalized intensity from four replicates is represented by the color of the corresponding cell in the matrix. Green, black and red cells, respectively, represent transcript levels below, equal or above the median abundance across all conditions. Color intensity reflects the magnitude of the deviation from the median (see scale at the bottom). The graphs on the left of the dendrogram represent the averaged Natural Log of normalized data ± SEM of the genes in nine major clusters. Gene expression ratio between naïve and CA together with statistical significant changes ($P < 0.05$; *naïve vs. CSTA, †naïve vs. USTA and ‡naïve vs. CA) are shown on the right of the matrix. Functional classification of MRGs is represented in a column on the right of the figure where each functional classes or subclasses are color coded. The name and GenBank accession number of MRGs uniquely regulated in CA are indicated in italic, whereas MRGs previously found to be differentially expressed in the hippocampus of water-maze-trained rats (Cavallaro *et al.* 2002) are indicated in bold. A complete list of the differentially expressed genes is available online at http://web.tiscali.it/sebastiano_cavallaro.

temporal gene expression comparison reported in the long term retention of learning and memory and further demonstrated the utility of a genomic approach as a means of dissecting the molecular basis of associative memory. This approach provides information on the gene expression changes that occur during physical activity, stress, learning and memory, allowing the identification of molecular targets and pathways whose modulation may generate new therapeutic approaches for facilitating learning and memory.

Passive avoidance learning

We have recently extended our genome-wide screenings to an additional behavioral animal model, a step-through passive avoidance test, known to require hippocampus-dependent learning and depend upon transcription (Stubley-Weatherly *et al.* 1996). In these experiments (D'Agata & Cavallaro 2003), conditioned animals (CA) were trained to avoid moving from the lighted to the darkened section of a conditioning chamber by delivering a foot shock when they entered the darkened section. Control rats included untrained (naïve) animals, and animals exposed to the unconditioned (USTA) or the conditioned (CSTA) stimulus. To verify that the trained rats in fact learned the passive avoidance task, learning was assessed in a comparable group of animals by evaluating the latency of step-through in a retention test. Twenty-four hours after the one-trial training period, only CA learned to associate stepping through the darkened chamber with the foot shock (Fig. 7a).

Hippocampal gene expression profiles in CA, USTA, CSTA and naïve animals were measured 6 h after training using microarrays containing 1263 genes relevant to neurobiology (D'Agata & Cavallaro 2003). When gene expression profiles of naïve animals were compared with those of CSTA or USTA, 46 and 60 genes, respectively, were found differentially expressed (Fig. 7b). These genes further demonstrate that physical activity and mild stress associated with behavioral training have a significant impact on hippocampal gene expression.

When gene expression levels in naïve animals were compared with CA, 38 MRGs were found (Fig. 7b). Among these, 21 genes were downregulated and 17 genes were upregulated. Some of these MRGs (21/38) were also differentially expressed in CSTA (16) and USTA (16) (Fig. 7b).

A hierarchical clustering method was used to group MRGs on the basis of similarity in their expression patterns (Fig. 7c). The most evident traits of the clustered data were that MRGs showed entirely different patterns of expression in CA vs. CSTA or USTA. Genes segregating into nine major branches of the dendrogram were assigned to nine clusters (Fig. 7c). Clusters 1–4 represent those genes, which were downregulated, whereas clusters 5–9 include those, which were upregulated in CA. Some of the MRGs, those differentially expressed between naïve and CA, were also affected by exposing the rats to the conditioned or the unconditioned stimulus alone, whereas others were uniquely induced when the two were associated and the animals were conditioned (Fig. 7c, clusters 2 and 8). Expression changes of MRGs in CSTA or USTA had different magnitudes or more often opposite trends than CA (Fig. 7c, clusters 1, 2, 3, 5, 8 and 9). As we have previously observed in water-maze-trained animal, learning, physical activity and mild stress associated with behavioral training involve common groups of genes. Their behavior in learning and memory, however, could be

1601183x, 2006, 3, Downloaded from https://onlinelibrary.wiley.com/doi/10.1111/j.1601-183X.2005.00159.x, Wiley Online Library on [13/10/2025]. Figure 8: Correlations between gene expression profiles and functional information. Complex correlations between gene expression profiles and functional information are needed to unravel the role of genes in the pathophysiology of learning and memory. Examples of functional information are listed on the right side of the figure and include gene annotations and phenotypic characteristics (any identifiable or observable structural or functional characteristic of an organism).

distinguished from unique patterns of gene expression as shown in the clustered data.

All of the MRGs identified have a recognized function and can be classified into different functional classes based on their translated product (Fig. 7c). Some of these genes have been previously related to synaptic plasticity, memory or cognitive disorders. Six of 38 MRGs found in the hippocampus of rats after passive avoidance training (Fig. 7c, shown in bold) were also differentially expressed in the same brain area following water-maze learning (Fig. 5f) suggesting common mechanisms of memory storage in different behavioral paradigms. For a complete description of the MRGs implicated by microarray technology during passive avoidance conditioning, the reader is referred to our previous study (D'Agata & Cavallaro 2003).

Conclusions

The characterization of expression patterns associated to the long-term retention of learning and memory in health (Cavallaro *et al.* 2001; 2002; D'Agata & Cavallaro 2003; Dubnau *et al.* 2003; Luo *et al.* 2001; Leil *et al.* 2003; Rampon *et al.* 2000) and disease (Blalock *et al.* 2003; D'Agata *et al.* 2002; Hata *et al.* 2001; Ho *et al.* 2001; Leil *et al.* 2002; Loring *et al.* 2001; Pasinetti & Ho 2001; Pasinetti 2001; Tudor *et al.* 2002; Yao *et al.* 2003) conditions has just started. Gene expression profiles unlock virtually unexplored frontiers, and we will learn as we explore them.

These 'early' studies are limited by the experimental design (animal strain, behavioral condition and time), technology (microarray platforms and number of genes) and computational analysis (normalization, filtering and statistical analysis) used. The value of these experiments will progressively increase as more is learned about the function of each gene and when software applications, like that we presented in this paper, will enable us to identify complex correlations existing between the genomic profiles obtained by microarray experiments and functional information (Fig. 8).

Although sure to be just the tip of the iceberg, the results already obtained point toward genes or sets of genes that may play critical roles in learning and memory. The discovery of these genes represents the key to developing novel and efficacious therapies to improve learning and memory, under normal conditions as well as in disorders that affect cognitive functioning, such as Alzheimer's disease.

ABSTRACT A protective vaccine is the only viable way to stop the spread of gonorrhea in the face of rising antibiotic resistance. However, the notorious phase and antigenic variation of *Neisseria gonorrhoeae* surface proteins remains one of the challenges in vaccine development. To facilitate vaccine advancement efforts, we carried out comprehensive bioinformatic analyses of sequence variation by comparing 34 gonorrhea antigen candidates among $>$5,000 clinical *N. gonorrhoeae* isolates deposited in the *Neisseria* PubMLST database. Eight protein antigens showed exceptional conservation by having a single allele variant distributed in $>$80% of isolates. An additional 18 vaccine candidates were represented by $\leq$3 alleles in $>$50% of *N. gonorrhoeae* isolates globally. Phylogenetic analyses highlighted closely related antigen variants and additionally showed that AniA and FetB were the closest between *N. gonorrhoeae* and *N. meningitidis*. Up to 44% of *N. meningitidis* alleles for both antigens have premature stop codons, suggesting differential expression. Mapping polymorphisms to the available three-dimensional structures of 12 antigens revealed low-frequency surface polymorphisms. PorB and TbpB possessed numerous high-prevalence polymorphic sites. While TbpA was also highly variable, conserved loops were nonetheless identified. A high degree of sequence conservation, the distribution of a single antigen variant among *N. gonorrhoeae* strains globally, or low-frequency sequence polymorphisms in surface loops make ACP, AniA, BamA, BamE, MtrE, NspA, NGO0778, NGO1251, NGO1985, OpcA, PldA, Slam2, and ZnuD promising candidates for a gonorrhea vaccine. Finally, the commonly used *N. gonorrhoeae* FA1090 strain emerges as a vaccine prototype, as it carries antigen sequence types identical to the most broadly distributed antigen variants.

IMPORTANCE *Neisseria gonorrhoeae*, the Gram-negative bacterium responsible for the sexually transmitted infection gonorrhea, is categorized as a high-priority pathogen for research and development efforts. *N. gonorrhoeae*'s "superbug" status, its high morbidity, and the serious health impact associated with gonorrhea highlight the importance of vaccine development. One of the longstanding barriers to developing an effective vaccine against *N. gonorrhoeae* is the remarkable variability of surface-exposed antigens. In this report, we addressed this roadblock by applying extensive bioinformatic analyses to 34 gonorrhea antigen candidates among $>$5,000 clinical *N. gonorrhoeae* isolates. Our studies are important, as they reveal promising, conserved gonorrhea vaccine candidates and aid structural vaccinology. Moreover, these approaches are broadly applicable to other infectious diseases where surface antigen variability impedes successful vaccine design.

In-depth bioinformatics profiling of gonorrhea antigens' variability for rational vaccine development

Received 23 September 2020
Accepted 8 January 2021
Published 3 February 2021

Development of vaccines against many infectious diseases and cancers has been hampered by immune system evasion strategies, including variability of surface antigens (1–3). The pathogenic *Neisseria* species, *Neisseria gonorrhoeae* and *Neisseria meningitidis*, are notorious for their ability to alter their surface proteome. Both *N. gonorrhoeae* and *N. meningitidis* have three important surface structures capable of phase and antigenic variation (2), namely, lipooligosaccharide (LOS) glycan (4), opacity proteins (5), and type IV pilus (6), as well as 50 to 100 genes that undergo solely phase variation (2, 7). The success of vaccines against *N. meningitidis* serogroup B infections demonstrated that creative vaccine development strategies are necessary to circumvent the difficulties posed by antigen variability. Through reverse and rational vaccinology approaches, two meningococcal subunit vaccines, Bexsero (GSK; also known as 4CMenB) (8, 9) and Trumenba (Pfizer) (8, 10, 11), were developed and entered the market in 2014. Bioinformatic assessment of factor H binding protein conservation revealed its two immunologically distinct subfamilies, which prompted the inclusion of a representative of each subfamily in the final Trumenba vaccine (10–12). These successes suggest that a similar approach could benefit gonorrhea vaccine research, which has been focusing on a handful of antigens for years (13).

N. gonorrhoeae is classified as one of the five "urgent" antibiotic-resistant threats in the United States by the Centers for Disease Control and Prevention (CDC) (14). Until recently, the sole treatment regimen approved by the CDC was azithromycin combined with ceftriaxone (15, 16). However, this recommendation was changed to a single dose of ceftriaxone based on the increased occurrence of azithromycin resistance, the low incidence of ceftriaxone resistance, and antimicrobial stewardship concerns (17). A vaccine appears as the only sustainable line of defense against the detrimental health effects caused by the gonococcus, which include urethritis, cervicitis, proctitis, neonatal conjunctivitis and blindness, mucosal infection of the rectum and pharynx, and the facilitation of HIV transmission (18–21). The common hallmarks of urethral infection in men are purulent exudate and painful urination, while women may experience mild and nonspecific symptoms as well as dysuria and vaginal discharge (22, 23). However, many men and most women are asymptomatic (24, 25). If left untreated, gonorrhea can result in complications, including epididymitis, endometritis, pelvic inflammatory disease, and ectopic pregnancy (26, 27). In many countries, gonorrhea case rates are increasing and disparities in the overall disease rate and burden persist among sexual, gender, racial, and ethnic minorities as well as resource-limited populations (14, 28, 29). The CDC, its European counterpart, the ECDC, and the World Health Organization (WHO) have all emphasized the dire threat posed by drug-resistant gonorrhea (26, 27, 30). Vaccine development efforts must be expanded and accelerated to slow the spread of this disease (26).

Ever more powerful and useful genomics, proteomics, and bioinformatics tools are instrumental for broadening the repertoire of gonorrhea vaccine candidates and facilitating vaccine development. For instance, quantitative proteomic and immunoproteomic studies identified over 20 new gonorrhea vaccine candidates. These proteins are present at similar levels in *N. gonorrhoeae* cell envelopes of 19 diverse isolates (31, 32), including the 2016 WHO reference strains, and in native outer membrane vesicles (OMVs) of four commonly used laboratory strains (32). Further, high-throughput proteomics revealed their expression profiles under conditions relevant to host infection, including iron starvation, exposure to human serum, or anaerobiosis (33). These studies combined with data from omics profiling of *N. gonorrhoeae* biofilms and during host infection provide invaluable insights about expression of all gonorrhea antigens currently being pursued in preclinical studies (13, 34–39). However, information about their antigenic variability globally, which is critically needed to identify conserved antigens with potential to develop broadly protective immunity against the highly variable *N. gonorrhoeae*, remains scarce. To address this gap, in this report we assessed the conservation of 34 candidate vaccine antigens discovered through different traditional (13) and proteomics-based reverse vaccinology efforts (31–33). We examined sequence variation and phylogenetic relationships among alleles for a single protein using sequence data from >5,000 *N. gonorrhoeae* isolates in the publicly available *Neisseria* multilocus sequence typing database (*Neisseria* PubMLST; https://pubmlst.org/organisms/neisseria-spp, sited at the University of Oxford) (40). This database contains sequence data from over 60,000 isolates of pathogenic and commensal *Neisseria* species collected worldwide, providing a rich resource for antigen diversity mining. We additionally mapped amino acid polymorphic sites to available antigen crystal structures. This approach provides a visual representation of protein conservation and illuminates conserved surface loops that could be incorporated into a vaccine delivery platform, thereby facilitating structural vaccinology. Polymorphic amino acids were mapped based on their prevalence in the population, rather than on the raw number of sequences available, to give more relevant insights about allele distribution. Finally, we also performed comparative analyses between each gonococcal protein antigen and its meningococcal homolog, to determine the level of conservation between the two species and to identify candidates for inclusion in a cross-protective vaccine against both *N. gonorrhoeae* and *N. meningitidis*.

The approaches we describe for *N. gonorrhoeae* are broadly applicable, as the PubMLST family of databases is home to sequence data from over 100 species and genera, including prokaryotic and eukaryotic pathogens (40, 41). New isolates are added to the database frequently, providing an up-to-date understanding of global protein variation.

RESULTS AND DISCUSSION

Antigen selection and workflow for bioinformatics mining. We selected the 34 gonorrhea protein antigens that were discovered through traditional approaches (13) and proteome-based reverse vaccinology studies (31–33). Excluded were the highly polymorphic opacity-associated proteins, candidates identified experimentally to be periplasmic, MetQ and MlaA (reported in references 38 and 42), and the small lipoprotein NGO2054 (33, 43) that has inconsistent annotations in PubMLST (e.g., annotated independently, as part of NGO2055, or lacks annotation). For comprehensive bioinformatics mining of *N. gonorrhoeae* antigens, we have developed the workflow presented in Fig. 1. The antigen sequences were downloaded according to the detailed instructions we previously described (41). Eight of the 34 antigens, including LbpA, PilQ, IgA2 protease, CsgG, MtrE, OpcA, TbpB, and ZnuD, contained various numbers of alleles disrupted by premature termination codon (see Table S1 in the supplemental material). The highest numbers of these alleles, 31, 18, and 16, were identified for LbpA, PilQ, and IgA2 protease, respectively. The presence of a premature stop codon may suggest phase variation events and most commonly results in loss of protein expression, a nonfunctional truncated protein, or, rarely, a protein with altered function (44). Therefore, alleles containing premature stop codons (89 in total) were excluded from further analysis. The *N. gonorrhoeae* strain FA1090 was used as a reference to identify the single nucleotide polymorphisms (SNPs) and single amino acid polymorphisms (SAAPs) in the obtained antigen sequences (Data Set S1). For each antigen, we mapped SAAPs identified in the most frequent antigen variant to the corresponding allele in *N. gonorrhoeae* FA1090 (Table 1). Finally, based on the prevalence data available from PubMLST, the frequencies of each SAAP were calculated, and the most common polymorphisms (found in ≥1% of the global population) were mapped to available protein crystal structures, either from *N. gonorrhoeae* or the closely related *N. meningitidis* (see Fig. 6 and 7).

NGO0778, SliC, PldA, NGO1985, BamE, ACP, Slam2, and NGO1251 are highly conserved gonorrhea vaccine candidates. To illustrate the distribution of each antigen nucleotide sequence variants in the global *N. gonorrhoeae* population, we graphed the percentage of isolates associated with each antigen allele (Fig. 2). Remarkably, over 90% of isolates carry an identical allele of NGO0778, SliC, PldA, NGO1985, and BamE. Further, between 80% and 90% of *N. gonorrhoeae* strains have a sole nucleotide sequence for acyl carrier protein (ACP), Slam2, and NGO1251. For 18 additional

FIG 1 Workflow for *N. gonorrhoeae* antigen variability mining. The *N. gonorrhoeae* and *N. meningitidis* (*Ng*/*Nm*) antigen (Ag) nucleotide sequences were downloaded from the PubMLST database (blue box). Geneious Prime 2020.1.2 software was subsequently used to perform analyses described below and outlined in the orange box. Sequences containing premature stop codons were eliminated. Nucleotide sequences were aligned using the Clustal Omega algorithm. To identify SNPs and SAAPs from the deduced amino acid sequence compared to the FA1090 allele sequence as a prototype, the Annotate & Predict tool was applied. In parallel, nucleotide sequences were translated to their respective amino acid sequences and aligned using the MUSCLE algorithm, followed by generation of neighbor-joining phylogenetic trees with the Jukes-Cantor genetic distance model. For proteins with available structural data, the proportion of isolates associated with each SAAP compared to the most common amino acid was calculated. Polymorphisms present in ≥1% of isolates were mapped to the protein three-dimensional structure using PyMOL (green box). SNP, single nucleotide polymorphism; SAAP, single amino acid polymorphism.

antigens—LprI, NGO1559, PilN, BamA, CsgG, NGO0425, Ng-MIP, ZnuD, LolB, NspA, OmpU, TamA, LptD, OpcA, PilQ, NGO1344, AniA, and MtrE—three or fewer alleles encompass >50% of *N. gonorrhoeae* isolates worldwide.

As expected, at the protein level, less unique SAAPs are present in the population for each antigen due to the presence of synonymous mutations. Thus, fewer protein variants would need to be included in a vaccine than the number of alleles would suggest (Table 1; Data Set S1). The most highly conserved antigen was BamE, with eight alleles and six distinctive amino acid sequences (Table 1; Data Set S1). Eight different amino acid sequences were present for SliC and NGO1251, whereas 10, 10, and 14 distinct amino acid sequence variants occurred for NGO1985, NGO0778, and ACP, respectively. The least conserved antigen, with 1,262 alleles and 1,229 unique amino acid sequences, was PorB. The dramatic difference in conservation between antigens illustrates the importance of this approach to evaluate the variability of candidate antigens before their testing in preclinical studies and inclusion in a vaccine. Our results showed that the FA1090 amino acid sequence is the most prevalent globally in 10 of the 34 antigens analyzed and diverges from the most common amino acid sequence by one or two polymorphisms in an additional 13 antigens (Table 1). The sole exception is LbpA, which has a premature stop codon in the FA1090 allele. Therefore, for this locus we used as the reference sequence the most common LbpA allele 16, which is carried, for instance, by the 2016 WHO reference strains WHO-M, WHO-P, WHO-U, and WHO-Y (45).

Cumulatively, these results suggest that the eight well-conserved proteins with >80% global homogeneity have the potential to protect against a wide range of *N. gonorrhoeae* strains if they are strong immunogens that are expressed on the bacterial cell surface during host infection. A combination of two or more conserved antigens could increase the vaccine coverage and effectiveness in comparison to a single-component vaccine. An example of this strategy is the *N. meningitidis* serogroup B vaccine Trumenba (Pfizer), which includes two representative factor H binding protein (fHbp) variants to provide broader coverage (10, 11). Finally, the antigen conservation data

TABLE 1 Summary of antigen polymorphism analyses[a]

Antigen (length range; mean mol wt)	No. of alleles	No. of SNPs	No. of unique amino acid sequences	No. of SAAPs	Position(s) of polymorphism(s) between FA1090 and most common allele (residue no. FA1090$_{aa}$ » allele$_{aa}$)[b]

[a] Antigens are listed in alphabetical order. aa, amino acids.

[b] Residue number includes gaps only if present in one of the two sequences. Dashes indicate a single amino acid deletion (gap). NA, not applicable; nsSNP, nonsynonymous single-nucleotide polymorphisms.

[c] Includes only those alleles without an annotated premature stop codon.

[d] Excludes allele annotated as atypical.

further validate the choice of FA1090 as a vaccine antigen prototype and a challenge strain in immunization/challenge experiments (32, 33, 36, 38, 39, 41, 46).

Phylogenetic analyses of gonorrhea vaccine candidates reveal evolutionarily distinct groups. We constructed phylogenetic trees to determine the evolutionary relationship between alleles and to assess distinct *N. gonorrhoeae* antigen families (Fig. 3 and 4; Fig. S1 to S3). The results of our phylogenetic analyses reflect and expand upon our prior observations (Table 1 and Fig. 2) by illustrating the number of alleles and how closely related they are on the amino acid level. The majority of alleles for each antigen were closely related, with notable exceptions. Although it is the most highly conserved of the antigens examined, BamE has a single allele that is divergent from the rest and forms an outgroup (Fig. 3A). Similar single-allele outgroups are observed for CsgG (Fig. 3B), LptD (Fig. 3D), Ng-MIP (Fig. 3F), NGO0425 (Fig. 4A), NGO1251 (Fig. 4B), OmpU (Fig. 4C), PilQ (Fig. 4E), and TbpB (Fig. 4G). These outgroups represent a minimal proportion of *N. gonorrhoeae* isolates for each antigen. NGO0425 has the outgroup that encompasses the most isolates, at 13 (0.2% of the isolates with data for this locus).

Our results are also consistent with the separation of several antigens into multiple subfamilies. We observed distinct subfamilies for IgA1 protease (Fig. 3C), MafA (Fig. 3E), PorB (Fig. 4D), and TbpB (Fig. 4G), discussed below. In our analysis, IgA1 protease clusters into two evolutionarily distinct groups, which correlate with the established

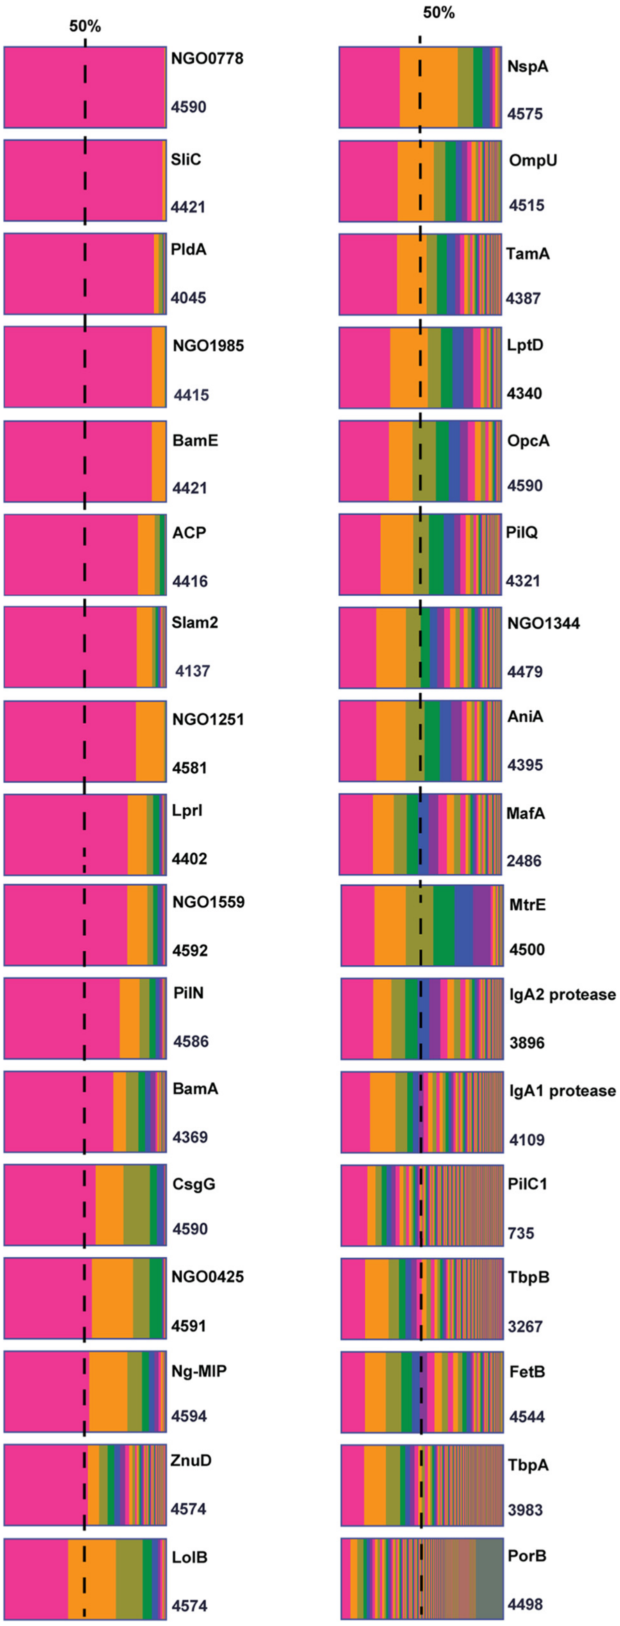

FIG 2 Distribution of each antigen nucleotide sequence variant in the global *N. gonorrhoeae* population. The percentages of *N. gonorrhoeae* isolates associated with each antigen allele were generated using GraphPad Prism 9. The total number of isolates with data for the antigen is indicated at the bottom right of each graph. The dotted line represents 50% of *N. gonorrhoeae* isolates. Antigens are arranged based on the prevalence of the most common allele in the *N. gonorrhoeae* global population.

FIG 3 Phylogenetic relationships of BamE, CsgG, IgA1 protease, LptD, MafA, and Ng-MIP among *N. gonorrhoeae* isolates. Neighbor-joining phylogenetic trees of antigens (as indicated below each tree) from *N. gonorrhoeae* were constructed in Geneious using the Jukes-Cantor genetic distance model. The FA1090 allele is designated in red text for each antigen. Subfamilies, when established, are indicated with curved lines. Antigens are organized in alphabetical order: BamE (A), CsgG (B), IgA1 protease (C), LptD (D), MafA (E), Ng-MIP (F).

classification into type 1 and type 2 IgA1 proteases (Fig. 3C) (47). Although both subfamilies function as autotransporter serine proteases that cleave the hinge region of the IgA1 heavy chain (48–52), they recognize different cleavage sites. Type 1 cleaves a proline-serine bond, and type 2 cleaves a proline-threonine bond immediately upstream of the type 1 recognition site (47). Further, the two variants have different secondary substrates (53–55), which may contribute to gonococcal virulence in ways that are not

FIG 4 Phylogenetic relationships of NGO425, NGO1251, OmpU, PorB, PilQ, TbpA, and TbpB among *N. gonorrhoeae* isolates. Phylogenetic trees of antigens were constructed in Geneious. The FA1090 allele for each antigen is designated in red text. Subfamilies, when established, are indicated with curved lines. The green-shaded region of TbpB phylogeny indicates the TbpB$_E$ subfamily. Antigens are listed in alphabetical order: NGO0425 (A), NGO1251 (B), OmpU (C), PorB (D), PilQ (E), TbpA (F), TbpB (G).

yet clear. Due to the evolutionary distance between the two protease types, a representative of each type will likely need to be considered for a vaccine, as *N. gonorrhoeae* isolates express one or the other but not both (47, 56).

MafA is an adhesin in the multiple adhesin family (*maf*) which binds to glycolipid cell receptors and mediates cell attachment (57). Up to five *maf* variants are encoded on horizontally acquired genomic islands in *N. gonorrhoeae* genomes (58). FA1090 possesses four copies of MafA: two pairs of identical loci, designated MafA 1/4 (NGO1067 and NGO1972) and MafA 2/3 (NGO1393 and NGO1584). Both pairs are returned as a single locus when the PubMLST database is queried. Our results show that the two MafA subtypes are evolutionarily distinct, while the alleles associated with each subtype are closely related (Fig. 3E). Therefore, a vaccine formulated with MafA should incorporate both subfamilies to account for isolates that may have one or the other.

The porin PorB (also known as protein I) is one of the most abundant proteins in the gonococcal cell envelope and acts primarily as a voltage-gated channel to facilitate ion exchange with the environment (59). *N. gonorrhoeae* isolates possess one copy of PorB in one of two allelic forms, PorB.IA or PorB.IB, which share only ~70% nucleotide sequence identity (60). The two protein forms are associated with different disease states: PorB.IA isolates are generally associated with disseminated infections, while PorB.IB-expressing strains usually cause localized urogenital infections (61, 62). PorB subtypes also contribute to fitness in the host in different ways (63–66). Consistent with the presence of two PorB subtypes in the *N. gonorrhoeae* population, this phylogenetic analysis split PorB alleles into two distinct clusters that correlate with PorB.IA (Fig. 4D, small cluster) and PorB.IB (Fig. 4D, large cluster). Although PorB.IA accounts for <10% of PorB sequences worldwide (426 of 4,498 isolates with PorB sequence data), representatives from both groups could be included in a vaccine, due to the difference in secondary function and extensive sequence diversity between the subtypes, as well as the dangerous disease phenotype associated with PorB.IA.

The outer membrane transferrin binding protein TbpA has previously been classified into two groups, based on the presence (D) or absence (N) of a deletion in variable region 3 (VR3) (67). However, our data do not support this classification. While we observe three clusters (two major and one minor) (Fig. 4F), both major groups have alleles with and without deletions in VR3. Instead, sequence differences in VR2, and to a lesser extent in VR1, appear to be the primary drivers of differentiation between the two main TbpA clusters. The possible reason for the differences observed between these reports is the small number of sequences analyzed in the previous study. Pajón et al. had access to only nine TbpA sequences in 1997 (67), while we compared TbpA variation among 638 allele sequences derived from nearly 4,000 isolates.

Finally, lipoprotein TbpB, which is involved in scavenging iron from human transferrin in conjunction with TbpA (68, 69), can be broadly classified into two isotypes based on protein size. Both *N. gonorrhoeae* and hyperinvasive meningococcal strains have type II TbpB (70). However, sequence analyses with 48 *Neisseria* isolates, including both pathogenic and commensal species, indicated that the two TbpB isotypes could be further divided into five families, from A to E. *N. gonorrhoeae* isolates are found in the TbpB$_C$, along with *N. meningitidis* and commensal species. TbpB$_E$ is composed exclusively of *N. gonorrhoeae* TbpB (71). Consistent with these results, phenotypic analysis clustered *N. gonorrhoeae* TbpB alleles into two groups (Fig. 4G). The two clusters are not as evolutionarily divergent as other groups observed in this study, likely because they are both members of the type II family. TbpB$_E$ (Fig. 4G, green-shaded area) accounts for the majority of alleles (247/320 alleles) and 80% of isolates.

These phylogenetic analyses illustrate the extent of sequence variation among the global *N. gonorrhoeae* population and highlight antigens' multiple variants, which may need to be considered in a vaccine design to account for distantly related protein families.

AniA and FetB are multi-*Neisseria* vaccine candidates based on phylogenetic analyses. We subsequently used phylogenetic comparisons to assess whether any gonorrhea vaccine candidate antigens could potentially be considered in a multi-*Neisseria* vaccine to protect against gonorrhea and meningococcal sepsis and meningitis simultaneously. While NGO1559 was highly conserved in *N. gonorrhoeae* (Fig. 2), it had no *N. meningitidis* homolog. With rare exceptions, *N. gonorrhoeae* protein variants clustered separately from their meningococcal homologs (Fig. 5; Fig. S4 to S8). Occasional instances of possible horizontal gene transfer between the species, where a gonococcal variant bundled with an otherwise exclusively *N. meningitidis* group or vice versa, could be observed for several antigens, including LptD, OmpU, Slam2, TamA, and TbpA (Fig. S4 to S8).

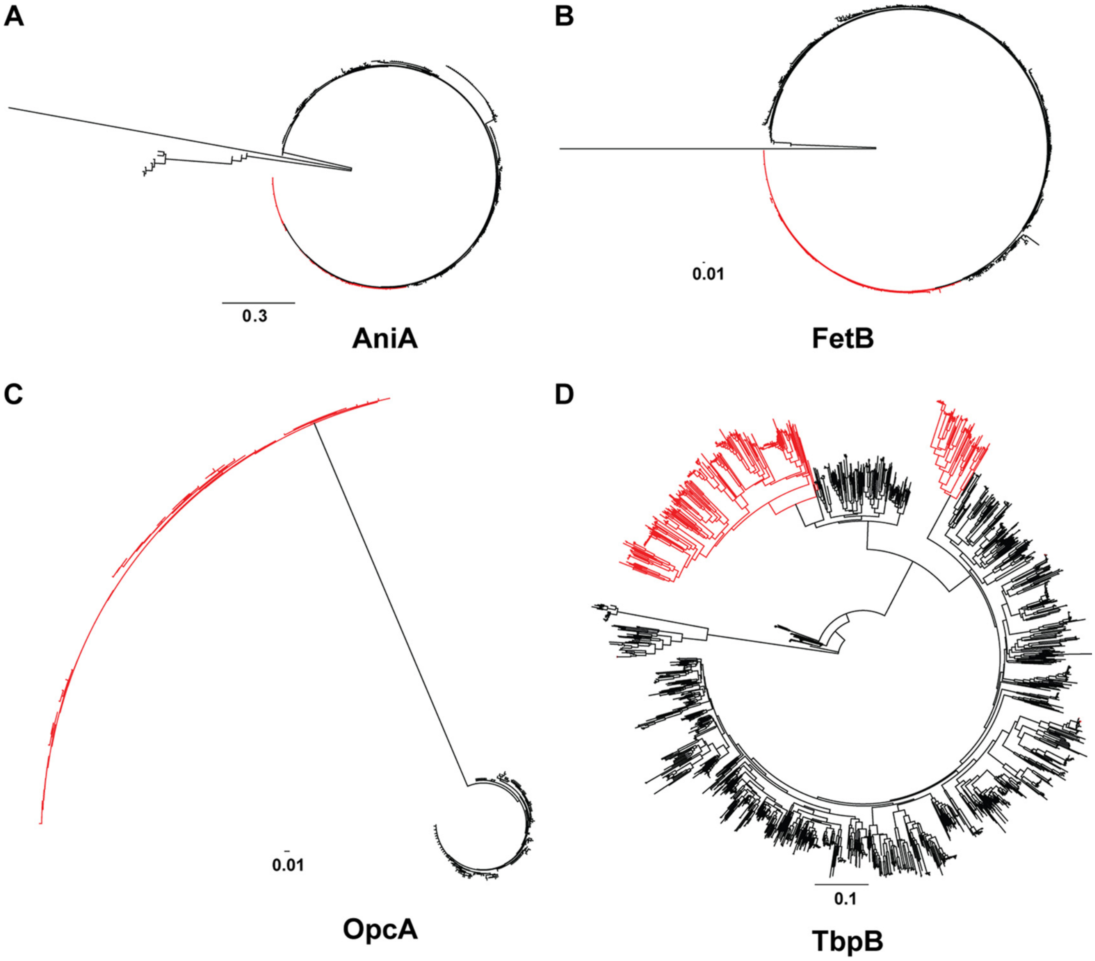

FIG 5 Phylogenetic relationships of AniaA, FetB, OpcA, and TbpB between *N. gonorrhoeae* and *N. meningitidis*. Neighbor-joining phylogenetic trees of indicated antigens from *N. gonorrhoeae* and *N. meningitidis* were constructed in Geneious using the Jukes-Cantor genetic distance model. *N. gonorrhoeae* alleles are designated using red branches. (A) AniaA; (B) FetB; (C) OpcA; (D) TbpB.

Based on phylogenetic comparisons between *N. gonorrhoeae* and *N. meningitidis*, the nitrite reductase AniA (Fig. 5A) and the component of the ferric enterobactin transport system FetB (Fig. 5B) seem the most useful candidates for inclusion in a multi-*Neisseria* vaccine. For both proteins, *N. gonorrhoeae* variants are in the same cluster as the *N. meningitidis* homologs or are in a closely related grouping. One consideration, however, is that 34% of *N. meningitidis* isolates have a frameshift mutation that abolishes AniA expression (72). Our analyses showed the existence of a higher percentage (43.8%) of AniA with premature stop codons in meningococcal isolates globally. Similarly, 34 alleles associated with 4,147 *N. meningitidis* isolates (28.8% of the population) encoded FetB sequences with premature stop codons.

The antigen subfamily separations seen within *N. gonorrhoeae* sequences (as discussed in a previous section) were further accentuated between *N. gonorrhoeae* and *N. meningitidis* isolates (Fig. 5C and D; Fig. S4 to S8). It was especially apparent for OpcA and TbpB. The gonococcal OpcA cluster was evolutionarily distinct from the *N. meningitidis* group (Fig. 5C). OpcA, an adhesin, was proposed as part of a DNA island imported into *N. gonorrhoeae* and *N. meningitidis* genomes from different species, based on the low homology between *N. gonorrhoeae* and *N. meningitidis* and the presence of a DNA uptake sequence upstream of the OpcA locus (73). From this standpoint, it appears as the least suitable candidate for a multi-*Neisseria* vaccine. For TbpB, *N.*

gonorrhoeae sequences formed two distinct groups completely separated from each other (Fig. 5D). The larger *N. gonorrhoeae* cluster corresponded to $\mathrm{TbpB_E}$ and did not have any *N. meningitidis* sequences associated with it (Fig. 5D). We noted that the majority of *N. gonorrhoeae* variants, although clustered separately from the *N. meningitidis* homologs, were moderately closely related to their meningococcal counterparts.

Together, these investigations suggest that while both AniA and FetB may be attractive candidates for a multi-*Neisseria* vaccine, additional, potentially species-specific antigens will need to be included to compensate for the lack of these proteins in substantial proportions of the *N. meningitidis* population.

Polymorphism mapping reveals conserved regions in vaccine antigens. To map antigen polymorphic sites, we used the available eight crystal structures of β-barrel-outer membrane proteins (OMPs) (Fig. 6) and four lipoproteins (Fig. 7) from either *N. gonorrhoeae* or the closely related *N. meningitidis*. In the past, we have performed similar analyses for the trimeric outer membrane channel component of the multiple transferable resistance (*mtr*) and fatty acid resistance (*far*) efflux pump systems, MtrE (74, 75), and the central component of the β-barrel assembly machinery (BAM) complex, BamA (41). Herein, however, we calculated the prevalence of each polymorphism within the *N. gonorrhoeae* population. This strategy allows the visual demonstration of the polymorphism frequency, in addition to its location, to determine whether several protein variants should be considered for a broad vaccine coverage (Fig. 6 and 7).

Importantly, only two low-prevalence polymorphisms (1 to 10%) were observed in surface loops of BamA (Fig. 6A). The highest-prevalence polymorphism, found in 20 to 30% of the *N. gonorrhoeae* population, was present in one of the periplasmic polypeptide transport-associated (POTRA) domains. An additional seven low-prevalence polymorphisms were found throughout the BamA β-barrel and POTRA domains. Remarkably, over 99% of *N. gonorrhoeae* isolates did not have any surface-exposed polymorphisms in MtrE (Fig. 6B). Per subunit, five polymorphisms (four in 10 to 20% of the population and one in 30 to 40%) are found in the equatorial domain of the periplasmic α-barrel, while a single high-prevalence polymorphism (40 to 50%) is present at the base of the periplasmic channel facing the pore's interior (Fig. 6B). Similarly, neisserial surface protein A (NspA), which contributes to *N. gonorrhoeae* serum resistance by binding factor H and factor H-like protein 1 (76), has a single low-prevalence polymorphism (1 to 10% of isolates) in one of its surface loops (Fig. 6C). Three more polymorphisms are present in the β-barrel portion of the protein; two are in 1 to 10% of isolates, and the third is in 30 to 40% (Fig. 6C). The adhesin OpcA exhibits three polymorphisms that are present in 10 to 20% of the population, two in a surface loop and one in the β-barrel portion, and one surface loop polymorphism that is present in 30 to 40% of the population (Fig. 6D). The dodecameric OMP antigen PilQ (77, 78) exhibited a single polymorphic site per subunit, within the structural data available for the periplasmic domains of *N. meningitidis* PilQ (78), that diverged in 20 to 30% of isolates (Fig. 6E). Further, no three-dimensional data are available for PorB.IB, despite its being the more prevalent subtype. However, mapping PorB.IA variants to the structure revealed extensive differences in all surface-exposed loops and, to a smaller degree, within the β-barrel itself (Fig. 6F). TbpA was highly variable, especially in a series of extracellular loops that extend ~60 Å above the cell surface (Fig. 6G) (79). This portion included eight sites that diverged from the most common sequence in 50 to 70% of isolates, along with five of the six sites that are polymorphic in 40 to 50% of the population. However, with the exception of D722 (polymorphic in 1 to 10% of isolates), the residues responsible for binding human transferrin were conserved in >99% of the *N. gonorrhoeae* population (80). In contrast, the zinc uptake protein ZnuD (TdfJ) was highly conserved and had only two surface loop polymorphisms found in 1 to 10% of the population within regions of the protein with available structural data (Fig. 6H).

Finally, ACP showed remarkable conservation of the four lipoprotein vaccine candidates with existing structural information (Fig. 7). The three-dimensional structure of *N. gonorrhoeae* ACP (81) did not incorporate any polymorphisms present in ≥1% of the

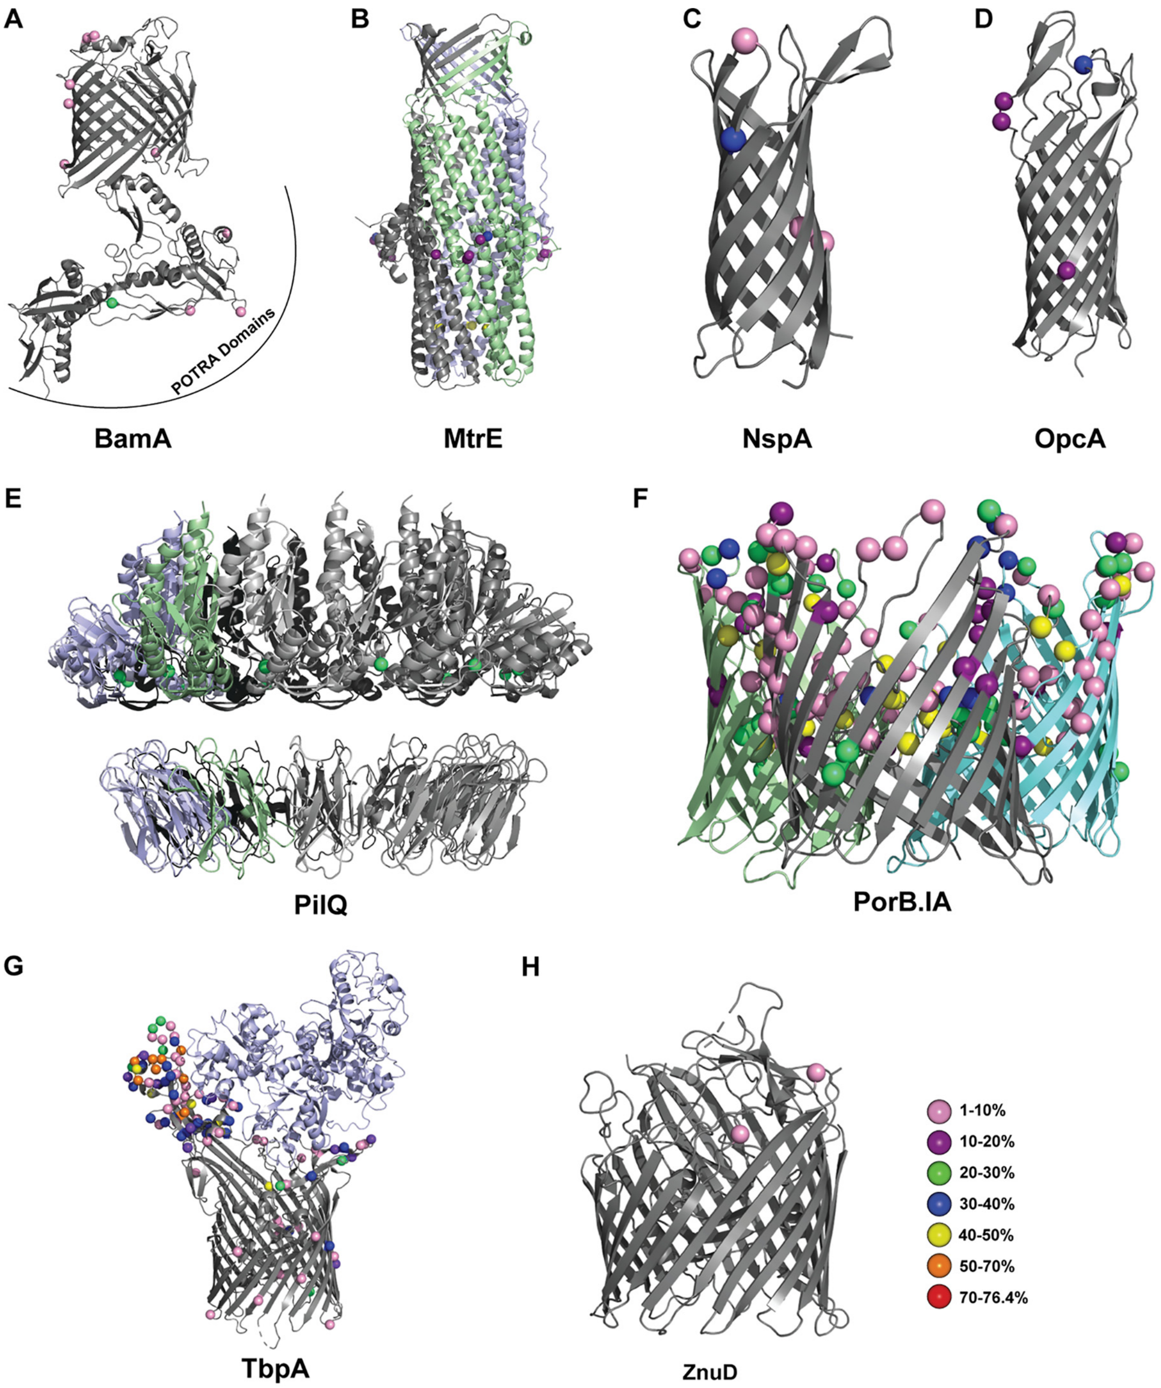

FIG 6 Polymorphism mapping to β-barrel outer membrane protein vaccine candidates. Polymorphic amino acid sites, weighted by the proportion of isolates associated with each polymorphism, were mapped to the structures of BamA (PDB accession no. 4K3B) (A), MtrE (4MT0) (B), NspA (1P4T) (C), OpcA (1K24) (D), PilQ (4AV2) (E), PorB.IA (4AUI) (F), TbpA (3V8X) (G), and ZnuD (4RVW) (H). When applicable, the biologically relevant multimers are shown, with individual monomers in different colors. Human transferrin associated with TbpA is shown in light blue. The polymorphic site color coding used in the figure is as follows: pink, 1 to 10%; purple, 10 to 20%; green, 20 to 30%; blue, 30 to 40%; yellow, 40 to 50%; orange, 50 to 70%; red, 70 to 76.4%.

population (Fig. 7A). Each subunit of the AniA trimer had four low-prevalence polymorphic sites (1 to 10%) and two sites divergent in 10 to 20% of the population (Fig. 7B). Each subunit of the BamE dimer possessed a single low-prevalence site (1 to 10% of the population) (Fig. 7C). TbpB was the most highly polymorphic lipoprotein examined,

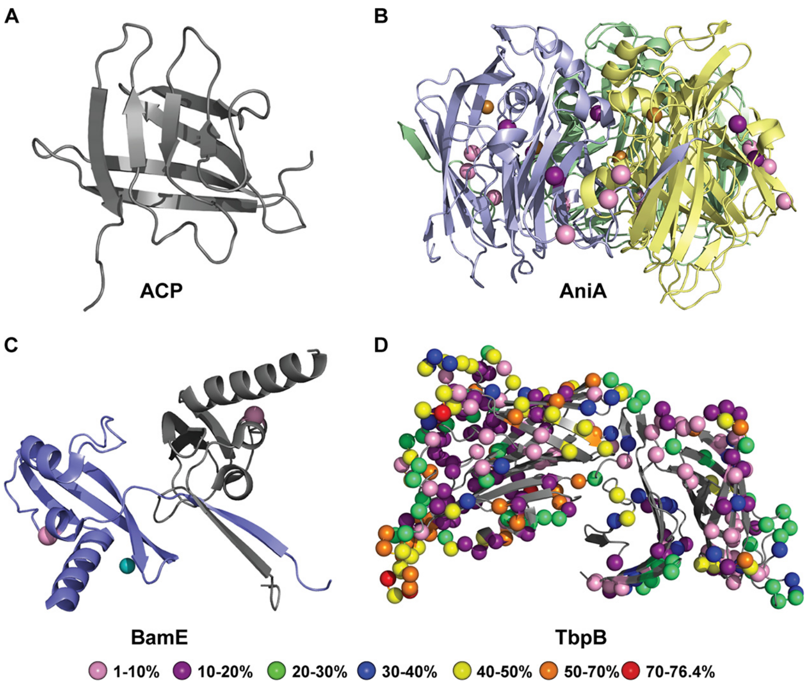

FIG 7 Polymorphism mapping to lipoprotein vaccine candidates. Polymorphic sites, weighted by the proportion of isolates associated with each polymorphism, were mapped to the structures of ACP (6GQ4) (A), AniA (5TB7) (B), BamE (5WAM) (C), and TbpB (3V8U) (D). When applicable, the biologically relevant multimers are shown, with individual monomers in different colors. Copper and zinc ions associated with AniA and BamE are designated by copper-colored and cyan spheres, respectively. Polymorphic site color coding is as follows: pink, 1 to 10%; purple, 10 to 20%; green, 20 to 30%; blue, 30 to 40%; yellow, 40 to 50%; orange, 50 to 70%; red, 70 to 76.4%.

with 379 polymorphic sites present in ≥1% of the global *N. gonorrhoeae* population (Fig. 7D). One hypervariable site diverged from the most common sequence in 76.4% of isolates. Including this site, four positions were polymorphic in >70% of the population, and 31 variants were present in 50 to 70% of isolates.

Cumulatively, these analyses showed that with the exception of PorB, TbpA, and TbpB, all of the OMPs and lipoproteins examined showed relatively few polymorphisms, particularly in the surface-exposed loops that are the most important from the vaccine design standpoint. Thus, BamA, MtrE, NspA, OpcA, ZnuD, ACP, AniA, and BamE appear as promising gonorrhea antigens. Several loops within the TbpA pore are highly conserved and could represent attractive targets for a vaccine that employed recombinant protein loops rather than the entire protein. A vaccine comprising the extracellular TbpA epitopes that elicits functional antibody responses targeting the transferrin binding pocket and occluding the pore might inhibit TbpA function. Similarly, thorough consideration and design would be necessary for TbpB. Indeed, a structure-based design to develop chimeric antigens to circumvent pathogen diversity has been successful in experimental vaccines against both bacterial and viral pathogens (82–85).

Conclusions. This is the first large-scale assessment of gonorrhea vaccine antigen variability. Evaluation of allele distributions revealed that >50% of *N. gonorrhoeae* isolates worldwide had three or fewer alleles for 23 antigens (Fig. 2). Among those, eight were exceptionally well conserved, with a single allele accounting for >80% of global isolates. Generation of phylogenetic trees indicated that the majority of antigens had closely related alleles and also revealed distinct subfamilies for IgA1 protease, MafA, PorB, and TbpB, consistent with classifications established in the literature (Fig. 3). Importantly, mapping polymorphic sites to structural data for 12 antigens showed that the majority of surface-exposed regions were identical in >90% of the global *N.*

gonorrhoeae population (Fig. 6 and 7). Notable exceptions were PorB.IA, TbpA, and TbpB, which were highly polymorphic. However, our analysis revealed conserved surface loops of TbpA, associated with transferrin binding, that could be presented to the immune system separately from the rest of the protein by use of a delivery system, for instance. Considering the high degree of conservation, the distribution among *N. gonorrhoeae* strains globally, or the low-frequency sequence polymorphisms in surface loops suggests that ACP, AniA, BamA, BamE, MtrE, NspA, NGO0778, NGO1251, NGO1985, OpcA, PldA, Slam2, and ZnuD are promising candidates for a gonorrhea vaccine. Together, these results can inform gonorrhea vaccine development, including structural vaccinology efforts, by identifying conserved antigens, highlighting regions of conservation, and mapping polymorphic sites. Change in an antigen epitope landscape, however, is one of the hindrances in design of a successful vaccine. Important additional factors include bacterial escape from immune surveillance by reducing an antigen's prevalence/expression on the cell surface and intrinsic and extrinsic host-related, environmental, behavioral, nutritional, and vaccine administration factors (1, 86, 87).

MATERIALS AND METHODS

Allele mining, SNP/SAAP, and phylogenetic analyses. Nucleotide or amino acid sequences for all antigens were downloaded from the *Neisseria* PubMLST database as previously described (41), between January and May 2020. Alleles annotated as atypical or with premature stop codons were excluded from analysis. Nucleotide sequences were aligned in Geneious Prime 2020.1.2 using the Clustal Omega algorithm. The FA1090 allele was set as the reference sequence, automated SNP/SAAP annotation was performed in Geneious, and the results were exported to Excel. The FA1090 LbpA allele possesses a premature stop codon, so the most common allele (16) was used as the reference sequence for this locus (see Data Set S1 in the supplemental material). For phylogenetic and polymorphism mapping analyses, nucleotide sequences were translated and aligned by Muscle in Geneious. Neighbor-joining trees were assembled from aligned amino acid sequence data for each antigen by using the Jukes-Cantor distance model (88) in Geneious.

Allele proportion analysis. Using data from the two-field breakdown table from PubMLST, the allele number and the number of isolates associated with each allele were imported into GraphPad Prism v8.4.3 for Mac. "Parts of whole" graphs were generated automatically.

Polymorphism mapping. The applicable crystal structure sequence was aligned against translated sequences from all antigen alleles using Muscle in Geneious. The crystal structures of the following proteins were used in this analysis: ACP (PDB accession no. 6GQ4) (81), AniA (5TB7) (89), BamA (4K3B) (90), BamE (5WAM) (91), MtrE (4MT0) (92), NspA (1P4T) (93), OpcA (1K24) (94), PilQ (4AV2) (78), PorB.IA (4AUI) (95), TbpA (3V8X) (80), TbpB (3V8U) (80), and ZnuD (4RVW) (96).

The number of isolates associated with each polymorphic site in the alignment was calculated and divided by the total number of isolates with data for each antigen to determine the proportion of the population that possessed each polymorphism (number of isolates with polymorphism/total number of *N. gonorrhoeae* isolates). The polymorphisms associated with >1% of isolates were mapped to structural data using PyMOL (https://pymol.org), as previously described (41).

ACKNOWLEDGMENTS

We thank the reviewers for insightful and detailed comments about our work.

This work was supported by National Institute of Allergy and Infectious Diseases grants R01AI117235 and U19 AI144180 (5967 and 5973).

The content is solely the authors' responsibility and does not necessarily represent the official views of the NIH. The funding sources had no role in study design, in collection, analysis, or interpretation of data, in manuscript preparation, or in the decision to submit the manuscript for publication.

A.E.S. developed and designed the study. B.I.B., R.A.Z., and A.K.H. collected and analyzed data. B.I.B., A.K.H., and A.E.S. wrote the manuscript. All authors provided feedback on the manuscript and approved the final version to be submitted. We attest that we meet the International Committee of Medical Journal Editors (ICMJE) criteria for authorship.

Abstract

Glioblastoma is the most aggressive malignant primary brain tumor with a poor prognosis. Glioblastoma heterogeneous neuroimaging, pathologic, and molecular features provide opportunities for subclassification, prognostication, and the development of targeted therapies. Magnetic resonance imaging has the capability of quantifying specific phenotypic imaging features of these tumors. Additional insight into disease mechanism can be gained by exploring genetics foundations. Here, we use the gene expressions to evaluate the associations with various quantitative imaging phenomic features extracted from magnetic resonance imaging. We highlight a novel correlation by carrying out multi-stage genomewide association tests at the gene-level through a non-parametric correlation framework that allows testing multiple hypotheses about the integrated relationship of imaging phenotype-genotype more efficiently and less expensive computationally. Our result showed several novel genes previously associated with glioblastoma and other types of cancers, as the LRRC46 (chromosome 17), EPGN (chromosome 4) and TUBA1C (chromosome 12), all associated with our radiographic tumor features.

Author Manuscript

grade into low-grade glioma, anaplastic glioma, and glioblastoma. The most common and aggressive type of glioma in adults is glioblastoma (GBM), which gives to the affected patient average survival time of only 10 to 18 months. The known molecular classification of GBM into classical, mesenchymal, neural and proneural subtypes is relatively accepted to be related to the expression of EGFR, NF1 and PDGFRA/IDH1 genes [1].

Imaging, specifically magnetic resonance imaging (MRI), can offer data towards promising biomarkers reflecting underlying tumor pathology and biological function. If imaging phenotypes of GBM obtained from routine clinical MRI studies can be associated with specific gene expression signatures, quantitative imaging phenotypes will serve as non-invasive surrogates for cancer genomic events and provide valuable information as to the diagnosis, prognosis, and optimal treatment.

Several radiogenomic studies have been carried out for many diseases [8–16]. For instance for schizophrenia pairs of SNP/Gene and MRI features have been mapped by using PLINK [8], and Parallel-ICA showed promising results [9]. Batmanghelich et al. [10] proposed a Bayesian framework to relate imaging and genetic data to phenotypes exploiting connection among these data modalities simultaneously in Alzheimer. Recently, correlations of connectomic features have been related to genes which are known to be related to Alzheimer progression [11]. In contrast to Alzheimer's disease and schizophrenia, glioma lesions are generally not spread all over the brain, and local features from MRI can be used. An imaging-genomic analysis study [12], performed by using the tumor volume in T2-weighted FLuid-Attenuated Inversion Recovery (T2-FLAIR) images and large-scale genetic and micro-RNA expression probes demonstrated the potential for molecular subtyping and showed that the high median expression of POSTN gene results in a significant decrease in survival, and for that they used ANOVA and Tukey-Kramer test. Other studies [13,14] showed correlations between image feature annotations and expression of genes with glioma molecular subtypes [1]. Specifically, Gutman et al. [13] found a significant association between contrast-enhanced tumor and these molecular subtypes [1], where proneural type expressed by PDGFRA/IDH1 gene showed low levels of contrast enhancement, and the classical type (i.e., primarily described by EGFR amplification) correlates with the increased percentage of contrast enhancement. The study used sher exact statistics.

Recent population-based studies have assessed the anatomical location of GBM in relation to distinct clinically-relevant molecular characteristics, and have identified the spatial distribution of the tumors being descriptive of their molecular status [14,17–22]. Furthermore, the emerging research direction of radiomics has shown promise that texture analysis of the various tumor sub-regions in radiographic imaging can also be informative of the tumor's molecular characterization [23–25]. Furthermore, using MRI features for GBM lesions, including texture and shape features, Haruka et al. proposed a classification imaging method and found three clusters of GBM patients [35]. In their method, they integrate copy number and gene expression data to estimate the molecular pathway activity and show that the three clusters reveal not only different molecular characteristics but also different survival probabilities.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

The purpose of this paper is to identify significant associations between gene expressions, across the whole genome, and quantitative imaging phenomic features extracted from multi-modal MRI brain scans of patients diagnosed with de novo primary GBM. In line with the pre-mentioned studies, here we focus on evaluating the spatial location and texture features of GBM and investigate their associations with gene expressions.

2 Materials and Methods

2.1 Data

For the quantitative association analysis conducted here, we utilized a retrospective cohort of 135 de novo primary GBM patients from the TCGA-GBM collection [6], with available pre-operative multi-modal MRI scans in The Cancer Imaging Archive (TCIA) [7] and corresponding molecular characterization in The Cancer Genome Atlas (TGCA). The multi-modal MRI data we utilized comprise native (T1) and post-contrast T1-weighted (T1Gd), T2-weighted (T2), and T2-FLAIR modalities. The TCGA-GBM subset of 135 patients were identified by Bakas et al. [4] as brain scans without any surgically-imposed cavity, and their co-registered and skull-stripped imaging were provided in the TCIA Analysis Results together with expert manually annotated segmentation labels for the various histologically-distinct tumor sub-regions, i.e. enhancing tumor (ET), non-enhancing tumor (NET), peritumoral edematous/invaded tissue (ED) (Fig. 1) [4,5]. The total sample size of GBM patients reduced to 88 after evaluating patients that had available imaging [6] and corresponding gene expressions. In total, we assessed expression energies for 17815 genes, 11 distinct descriptors of tumor spatial location (Fig. 2), and 517 radiomic/texture features (Fig. 2) for each patient's brain tumor scan [2,4,5].

2.2 Quantitative Imaging Phenomic Features

Radiomic/Texture Features.—We extracted an extensive panel of quantitative texture features, volumetrically (in 3D), for each tumor sub-region as provided by the expert annotations, across all available modalities. Specifically, the texture features we evaluated (i) capture global characteristics (i.e., variance, skewness, kurtosis) of each sub-region's intensity distribution on each modality, and (ii) include features based on Gray-Level Co-occurrence Matrix (GLCM) [26] (Fig. 2), Gray-Level Run-Length Matrix (GLRLM) [27–30], Gray-Level Size Zone Matrix (GLSZM) [28–30], and Neighborhood Gray-Tone Difference Matrix (NGTDM) [31].

Spatial Distribution Patterns.—Beyond texture features, we collected discrete spatial information about the anatomical location of each tumor on each brain scan (Fig. 2). To obtain these spatial distribution patterns we registered all brain tumor scans in a standardized healthy atlas space using an iterative Expectation Maximization framework [3], while incorporating a biophysical tumor growth model (based on a reaction-diffusion-advection model [32–34]) to account for tumor mass effects in the brain parenchyma. We then retrieved the spatial distribution of each tumor according to the discretized anatomical locations of the (i) specific lobes (i.e., frontal, temporal, parietal, occipital), (ii) insula, (iii) basal ganglia, (iv) fornix, (v) cerebellum, and (vi) brain stem. In addition, we also included

Author Manuscript

Author Manuscript

Author Manuscript

Author Manuscript

as distinct features the distances of (i) the tumor core (defined as the union of ET and NET), and (ii) the ED, from the ventricles.

To produce these quantitative features we have utilized GLISTRboost. Specifically, in the process to produce segmentations of the various tumor subregions, the generative part [37] of GLISTRboost, following an Expectation Maximization framework registers a healthy population probabilistic atlas to glioma patients' brain scans while incorporating a biophysical glioma growth model to account for mass effects. Then, after converting the predicted segmentation in the healthy atlas space, the percentage of the tumor core (i.e., enhancing and non-enhancing tumor) is calculated on each of the brain lobes in this healthy atlas.

2.3 Data Analysis

Initially, we combined the two types of data (imaging - genetics) using the patient ID as a primary column. As a first stage, we used the gene expressions and the spatial distribution patterns to perform a non-parametric test of association. To assess the associations, we computed the Spearman correlation coefficient (r_s) between the gene expressions, individually, as a with each of the spatial distribution patterns described in Sect. 2.2. We then assessed the significant of the correlation coefficient by calculating the p-values as described below.

For each quantitative feature and each gene, We obtained the p-value associated with Spearman correlation coefficient test statistic. That is, the p-value of the correlation between a single gene expression with a single feature of the tumor's location in the brain. The Spearman correlation coefficient model for a given feature (y) and given gene expression (x) is;

$$r_s = 1 - \frac{6\sum_{i=1}^{i=N} d_i^2}{N\left(N^2 - 1\right)} \quad (1)$$

Where d_i is the difference between the ranks of x_i and y_i, and N is 88; representing the number of GBM patients [38]. r_s can take any real value between +1 and −1; +1 represents a strong positive association, −1 means a perfect negative association and 0 indicates no association between the ranks of x and y. Our hypothesis of interest is:

H_0: There is no association between the gene expression and the tumor's feature under study

vs

H_a: There is an association between the gene expression and the tumor's feature under study, alternatively:

H_0: $\mathrm{r_s} = 0$ $vs\ H_0 : r_s \neq 0$

To determine the significance of r_s, one can use the t test statistic defined as

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

$$t_c = r_s\sqrt{\frac{n-2}{1-r_s^2}}, \quad (2)$$

t_c follows approximately the Student's t distribution with a $N2$ degrees of freedom under the null hypothesis [38]. At a certain significance level, the calculated value of t_c can be compared to the table value obtained from the Student's t distribution (as described previously). The significance of r_s can also be determined using the p-value, which is simply the integration, or the area under the curve from t_c to infinity.

Briefly, in this first stage, the association test was initially conducted to six features of the tumor location (Sect. 2.2). More specifically, for each gene, we computed six p-values, then considered only the minimum p-value at each gene (see Fig. 3 for the analysis workflow). The latter is referred to as meta-analysis in Fig. 3 (step(c)). All results reported in Sect. 3 use the summary statistics of the meta-analysis. Moreover, out of the all the association results, we excluded all the genes with p-values greater than or equal 0.05. Here we meant to exclude the genes that have very low (and not significant) association with the spatial pattern, which we believe is an important phenotype. This step is referred to as (d) in Fig. 3. In the second stage, we proceeded with all the genes with p-value less than 0.05, excluding the least significant genes, and we carried the same analysis as in the first stage but using the radiomic features (Sect. 2.2. Table 1 shows the thresholds at both 5% and 10% significance level), along with the number of genes used and remained in each stage.

It is worth mentioning that, out of the total number of genes, we were able to annotate 15009 genes and assign them to their defined physical locations in the DNA. We carried on the first stage of the analysis using those genes (Table 1).

3 Results

The incidence of tumors specific for region is summarized in Table 2. The Manhattan plot for the p-values obtained from the meta-analysis is illustrated in Fig. 4. The plot shows two horizontal lines which associate with the thresholds of 5% significance level (top line), and 10% significance level (bottom line), after correcting for multiple comparisons. The x-axis is the physical position of genes in the DNA, and the y-axis is the negative $log10$ of the p-values. Figure 4 also shows the qq-plot of all the genes used in the association analysis. Likewise, each dot corresponds to a p-value of a single gene and $-log10$ of the p-value is used instead. The qq-plot reported with each Manhattan plot, and it compares the observed distribution of p-values (y-axis) to the expected distribution (x-axis), for each gene tested, where the diagonal line is the null distribution.

Table 3 shows (only) the highest ten p-values and the corresponding genes of the first stage of the analysis. In this stage, non of the p-values was less than $3.3e^{-6}$ or $6.7e^{-6}$ (see Table 1); therefore, no gene was significantly associated with any of the features. Table 3 reports the gene symbol, its start and end position, the associated p-value and feature, and the chromosome.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

We then pruned the genes used in the previous stage to a smaller set, by removing the genes that have p-values less than 0.05. With the 5401 genes remaining, we took over the second stage and repeated the same analysis with the texture characteristics of the tumor. The Manhattan and qq-plot for the texture features are shown in Fig. 5, and Table 4 shows the top 10 significant genes. Total of significant genes in this stage is 37 (at 5% significance level).

4 Discussion

GBM is a fatal malignant disease that so far is incurable. The identification of genetic risk factors that affect the tumor characteristics improves our understanding of the underlying biological processes for GBM, and contribute to therapeutic discovery. In this study, we proposed a framework that allows quantifying the non-parametric correlations to test associations between gene expressions and different quantitative imaging phenomic characteristics of GBM. Our result has shown a high genetic enrichment through the Manhattan and qq-plots, especially for the texture features (Fig. 5).

Our results highlighted several genes that significantly associated with the tumor texture features, including *LRRC46, USP38, EPGN, TUBA1C, ZNF284, IPO8, MMP7, TLL2, TRIM55* and *UBAP1*, as the top ten significant genes (Table 4). However, there are, in total, 37 genes are significantly associated with the texture features (Fig. 5). EPGN expression associates significantly ($r_s = 0.501$, p-value = $6.542e{-}07$) with GLSZM LGZE in the T1Gd modality (Table 4). EPGN previously reported to be one of the top ten upregulated genes after EBLN1 silencing in oligodendroglia cells [39]. Moreover, the emergence of EPGN was marked in another study by Duhem-Tonnelle et al. in EGF ligands expression profile, between glioblastoma cell lines and biopsies [40]. Located at chromosome 4, USP38 ($r_s =$ -0.511, p-value = $3.648e{-}07$) [41]. Moreover, as it is illustrated in the Manhattan plot of the spatial features of the tumor (Fig. 4 and Table 3), no gene shows significant association with any of the location features. In addition to the latter, the number of GBM lesions in the cerebellum in clinical settings are quite rare [36], as also shown in our summary Table 2. Our study can give some insight into this rare type of GBM lesion. Nevertheless, the investigation excluding the patients having those lesions have to be repeated as a future work.

5 Conclusion

As the understanding of gliomagenesis grows, several medical imaging biomarkers and genetic variations can be identified, and new hypotheses can be formed. The hereby proposed genome-wide association framework aims at identifying differentially expressed genes that significantly correlate with various aspects of GBM. The identification of such genes may contribute to the development of targeted therapies that focus on the resistance mechanisms of individual patients.

Through the systematic testing of associations and shrinking of the number of genes at every stage, this pipeline facilitates the evaluation of various hypotheses and reduces the computational complexity. In future work, we plan to extend the study by integrating more

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

quantitative imaging phenomic tumor characteristics, inclusive of morphological, intensity, and volumetric descriptors, as well as parameters derived by biophysical tumor growth modeling.

Spatiotemporal genomic architecture informs precision oncology in glioblastoma

Jin-Ku Lee[1,2,13], Jiguang Wang[3–5,13], Jason K Sa[1,2,6,13], Erik Ladewig[3,4,13], Hae-Ock Lee[7], In-Hee Lee[1,2], Hyun Ju Kang[1,2], Daniel S Rosenbloom[3,4], Pablo G Camara[3,4], Zhaoqi Liu[3,4], Patrick van Nieuwenhuizen[3,4], Sang Won Jung[1,2,6], Seung Won Choi[1,2,6], Junhyung Kim[1,2], Andrew Chen[3,4], Kyu-Tae Kim[7], Sang Shin[1,2,6], Yun Jee Seo[1,2], Jin-Mi Oh[1,2], Yong Jae Shin[1,2,7], Chul-Kee Park[8], Doo-Sik Kong[2], Ho Jun Seol[2], Andrew Blumberg[9], Jung-Il Lee[2], Antonio Iavarone[10–12], Woong-Yang Park[6,7], Raul Rabadan[3,4] & Do-Hyun Nam[1,2,6]

Precision medicine in cancer proposes that genomic characterization of tumors can inform personalized targeted therapies[1–5]. However, this proposition is complicated by spatial and temporal heterogeneity[6–14]. Here we study genomic and expression profiles across 127 multisector or longitudinal specimens from 52 individuals with glioblastoma (GBM). Using bulk and single-cell data, we find that samples from the same tumor mass share genomic and expression signatures, whereas geographically separated, multifocal tumors and/or long-term recurrent tumors are seeded from different clones. Chemical screening of patient-derived glioma cells (PDCs) shows that therapeutic response is associated with genetic similarity, and multifocal tumors that are enriched with *PIK3CA* mutations have a heterogeneous drug-response pattern. We show that targeting truncal events is more efficacious than targeting private events in reducing the tumor burden. In summary, this work demonstrates that evolutionary inference from integrated genomic analysis in multisector biopsies can inform targeted therapeutic interventions for patients with GBM.

Most clinical trials for targeted therapy in GBM have shown limited clinical success[15]. Although recent genome-wide studies evaluating regional heterogeneity[9,11] and longitudinal GBM pairs[8,12,14,16] have suggested potential evolutionary models of the tumors, there is little understanding regarding which strategies can effectively use genomic data to inform targeted therapies. To identify such strategies, we analyzed somatic variants in 127 multiregion or longitudinal tumor specimens from 52 individuals with glioma: 42 individuals from the Samsung Medical Center (SMC), Seoul, and 10 individuals from The Cancer Genome Atlas (TCGA) GBM cohort[8,14,16] (**Supplementary Table 1**). Additionally, we analyzed the transcriptomes of 83 tumor specimens from 41 individuals (bulk) and 305 single cells from 7 samples for 3 individuals. Tumors were classified into four distinct groups according to the spatial and temporal features of tissue acquisition: tumors obtained from the same location at the same time (locally adjacent), tumors obtained from different locations at the same time (multifocal/multicentric; referred to as multiple)[17], and tumors obtained from local and distant recurrences at different times (longitudinal local and distant, respectively) (**Fig. 1a**).

We inferred clonal and subclonal alterations from cancer cell fractions in multiple sectors (Online Methods and **Supplementary Table 2**). The average mutation rate was 2.2 mutations/Mb for non-hypermutated samples, which is consistent with previous studies[2,14]. *IDH1* mutations mapping to Arg132 were clonal across all of the regions in IDH-mutant tumors[2,14] (6/6). *PIK3CA* mutations were always clonal and shared by all sectors (5/5), which is consistent with the results of our previous longitudinal analysis from tumor evolution directed graphs (TEDGs), in which we found that *PIK3CA* mutations are early events[14] (**Fig. 1b** and **Supplementary Fig. 1a**,**b**). Furthermore, *FGFR3-TACC3* fusions were highly expressed in all regions from two individuals[18]. These somatic variants, which are shared by all tumor regions, represent promising therapeutic targets[14,19], as they reflect truncal alterations in the evolutionary tree that are suspected to be present among all tumor cells. In contrast, *PTEN* alterations, including copy number deletions and mutations, were shared by 10 of 20 (50%) and 5 of 7 (71.4%) tumor sectors, respectively. Likewise, *EGFR* amplifications were observed as private events, exclusive to only one or two regions of the multisector

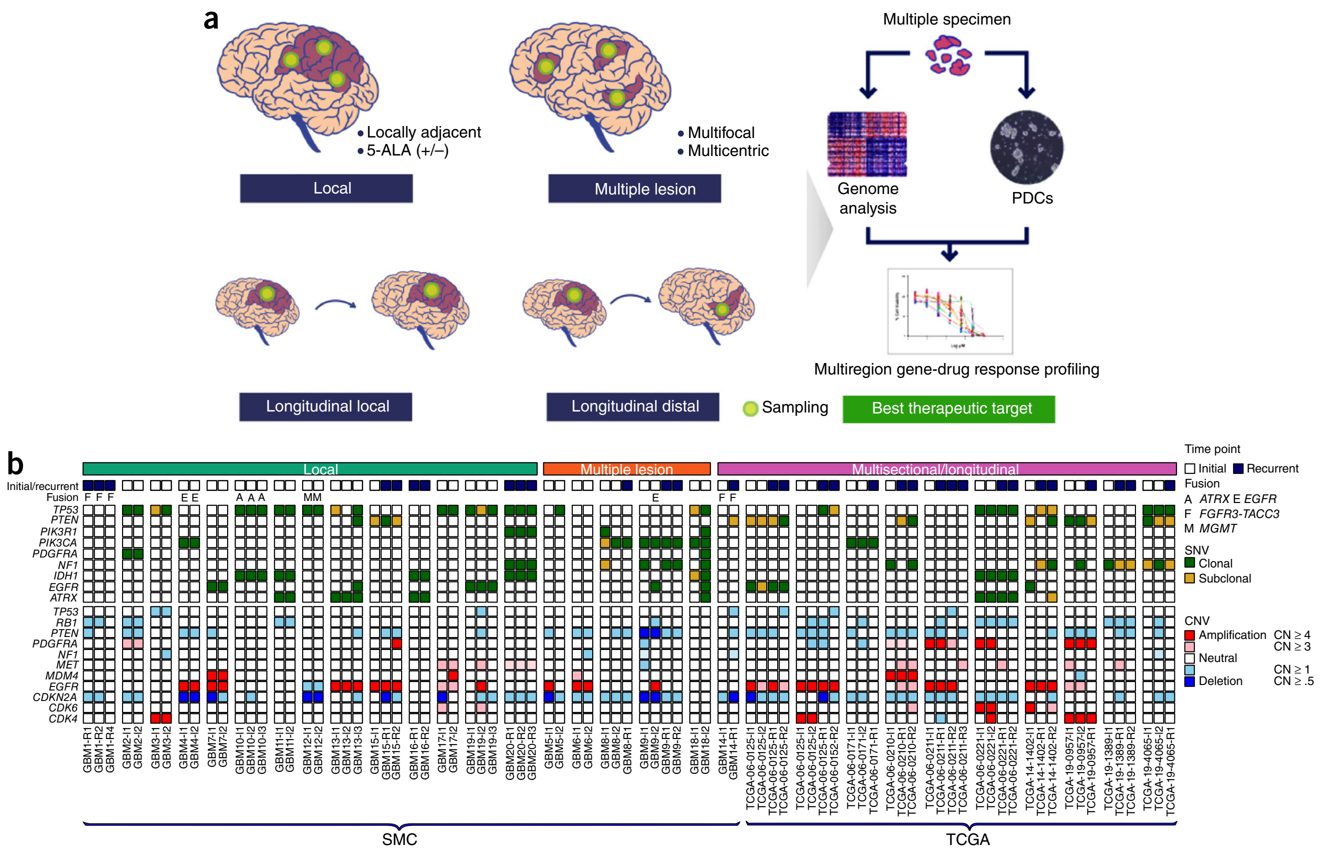

Figure 1 Mutational landscape of multiregion malignant glioma samples. (**a**) A schematic representation of glioma genomic heterogeneity and differential drug-response analysis. Human glioma specimens were acquired on the basis of their spatial order or longitudinal pairing and were subjected to genomic analysis for identification of tumor-initiating (truncal) events. PDCs, patient-derived cells; 5-ALA, 5-aminolevulinic acid. (**b**) Somatic mutations, including single-nucleotide variants (SNVs) and small insertions/deletions, copy number alterations, and gene fusions, for 83 glioma multiregion or multisector longitudinal specimens from 30 patients are shown. 34 locally adjacent tumor fragments from 14 patients, 13 multifocal/multicentric (referred to as multiple) tissues from 5 patients, and a longitudinal pair, GBM14, with leptomeningeal seeding were collected from the Samsung Medical Center (SMC). We also curated 34 multisector longitudinal tumor exomes and/or RNA sequencing data from 10 patients in The Cancer Genome Atlas (TCGA) cohort[8]. All somatic mutations called by SAVI with an allele frequency of >5% are shown. For each gene, we calculated copy number (CN) on the basis of Excavator results. Clonal alterations were determined using ABSOLUTE with a cancer cell fraction of >80% (Online Methods). CNV, copy number variation.

sample, in 4 of 15 (26.7%) of the *EGFR*-amplified tumors, including 2 multiple cases (GBM5 and GBM9). Furthermore, *EGFR* mutations were shared by 3 of 7 (42.9%) cases, including one harboring disjoint alterations, which are different genomic alterations in the same gene (GBM7-I1: p.Leu62Arg and p.Arg108Lys; GBM7-I2: p.Ala289Val and p.Cys624Ser), suggesting that partial genetic information from a single tumor biopsy can be inconclusive in assessing the potential benefit from EGFR-targeted therapy (**Supplementary Fig. 1b**,**c**).

To understand the association between spatiotemporal architecture and genetic relevance, we calculated Nei's genetic distances among multisector samples from the same individual (Online Methods). Genetic diversity was greater in multiple tumors than in locally adjacent tissues ($q = 4.7 \times 10^{-5}$, Wilcoxon rank-sum test; **Fig. 2a**), in distant recurrences than in local recurrences ($q = 1.4 \times 10^{-5}$, Wilcoxon rank-sum test; **Fig. 2a**), and in long-term recurrence than in short-term recurrences ($q = 2.9 \times 10^{-3}$, Wilcoxon rank-sum test; **Fig. 2a**). Multinomial logistic regression was applied to classify multisector sample pairs on the basis of their genomic features (**Supplementary Note**). This analysis highlighted that tumors from distant regions or long-term recurrences, separated by surgical intervals exceeding 18 months, constitute a distinct evolutionary scenario in GBM (**Fig. 2b**). In colorectal tumors, a Big Bang model[20] shows that cells from different biopsies of the same tumor share clonal and subclonal variants (**Fig. 2c**, left). In accordance with this model, samples taken from locally adjacent tumors shared a large proportion of clonal and subclonal events (**Supplementary Fig. 2a**,**b**). In contrast, multiple tumors contained fewer shared (more private) clonal mutations when compared to local tumors ($q = 1.86 \times 10^{-3}$, Wilcoxon rank-sum test; **Supplementary Fig. 2a**). We corroborated this finding by computing statistics on the space of evolutionary trees (evolutionary moduli spaces; Online Methods and **Supplementary Fig. 3**). Locally adjacent tumors clustered near the tip of the space, indicating a higher shared mutation ratio than that of multiple tumors ($P = 1.27 \times 10^{-2}$, Wilcoxon rank-sum test). These results indicate that, in contrast to locally adjacent tumors, geographically separated multifocal tumors and/or long-term recurrent tumors are seeded from distinct clones, a phenomenon we call the 'multiverse model' (**Fig. 2c**, right). Unlike the Big Bang model[20], in the multiverse model, tumor samples that are derived from different tumor masses share very few genomic alterations, indicating that tumor clones are geographically segregated at an early stage of evolution and that each clone acquires distinct private alterations, leading to the construction of multiple universes.

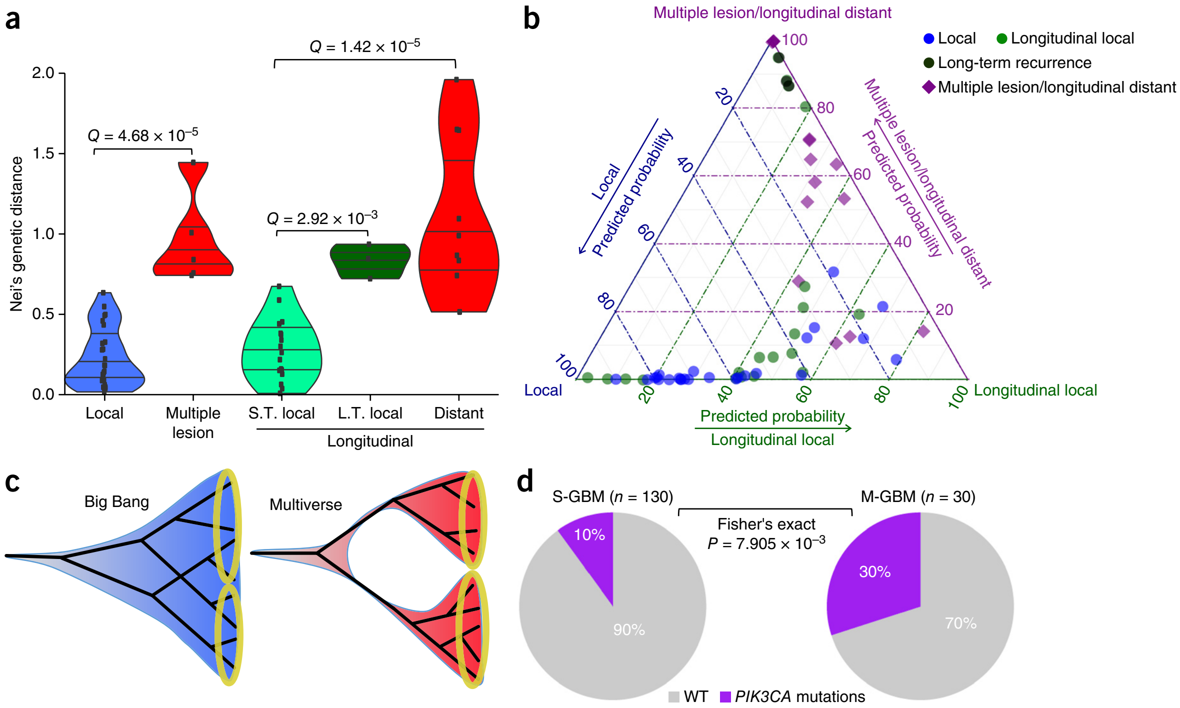

Figure 2 Comparison of genetic heterogeneity across glioma multisector and longitudinal samples. Patient samples were classified into five groups for comparative analyses: local, multiple lesion, S.T. (short-term) longitudinal local, L.T. (long-term) longitudinal local, and longitudinal distant. (**a**) Nei's genetic distances for each of the indicated groups are shown. *q* values were calculated by Wilcoxon rank-sum test and corrected for false discovery rate (FDR) using the Benjamini–Hochberg method. S.T. and L.T. local correspond to short-term (<18-month surgical interval) and long-term (≥18-month interval) recurrent tumors, respectively. The lines within each 'violin' represent the 25th, 50th, and 75th quantiles. *n* = 25 (local), 5 (multiple lesion), 17 (S.T. local), 3 (L.T. local), and 10 (distant). (**b**) Illustration of leave-one-out results from multinomial logistic regression. Each point represents one pair of samples, and the coordinates correspond to the probability that the pair is local, multiple lesion/longitudinal distant, or longitudinal local. L.T. recurrent samples were classified together with multiple lesion/longitudinal distant samples, indicating that they might follow the same evolutionary model. (**c**) Tumor evolution behind the Big Bang and multiverse models. The Big Bang model is represented as a mixture of tumor cells that share many clonal and subclonal alterations. The multiverse model is represented by a greater proportion of private events at a clonal level. (**d**) Pie charts show the frequencies of *PIK3CA* mutations in multifocal/multicentric glioblastomas (M-GBMs) (30%, 9/30) and solitary glioblastomas (S-GBMs) (10%, 13/130). WT, wild type. The *P* value was calculated using Fisher's exact test.

Next, we investigated the mutation profiles of GBMs with multifocal/multicentric lesions (M-GBMs) or solitary lesions (S-GBMs) in a total of 160 treatment-naive individuals from both the SMC and TCGA[17] cohorts (Online Methods, **Supplementary Figs. 4** and **5a**, and **Supplementary Table 3**). Notably, nonsynonymous mutations of *PIK3CA* were enriched in M-GBM (13/130 S-GBM and 9/30 M-GBM tumors; $P = 7.905 \times 10^{-3}$, Fisher's exact test; **Fig. 2d**). This conclusion remained the same in the *IDH1*-wild-type cohort (**Supplementary Fig. 5b**). *PIK3CA* induces multipotency of mammary tumors, suggesting that it has an associative role in tumor multiplicity[21]. Survival analysis indicated that both patients with M-GBM and *PIK3CA*-mutant patients had a worse prognosis than patients with S-GBM or wild-type *PIK3CA* (P = 0.0151 and 0.039, respectively, log-rank test; **Supplementary Fig. 5c**,**d**).

To further characterize the heterogeneity of expression profiles, we curated single-cell RNA–seq data from a total of seven different samples from three patients. Overall, expression-based cell subtypes were not clearly determined by location or time (**Fig. 3**), which is consistent with a previous report[10]. To make sure that this observation was not due to the limitations of this classification and to capture the transcriptional similarity among different cells, we used topological data analysis (Online Methods), a recently developed technique that summarizes and reduces the dimensionality of large data sets while retaining local high-dimensional structure[22,23].

GBM9 (**Fig. 3a–d**) consisted of samples from two initial tumors in the right and left frontal lobes and a recurrent tumor in the left frontal lobe that emerged after concurrent chemoradiotherapy (CCRT) and EGFR-targeted treatment (**Supplementary Note**). We found in bulk whole-exome sequencing (WES) and confirmed using ultra-deep sequencing (**Supplementary Table 4**) and single-cell analysis that cells from the recurrent tumor shared genomic and expression features with initial tumor cells from the left frontal lobe (**Fig. 3b** and **Supplementary Figs. 6–8**). Particularly, there were 61 somatic mutations shared by the left initial tumor and the recurrent tumor, while there were only 42 shared by the right initial tumor and the recurrent tumor. Single-cell transcriptome analysis showed *EGFR* expression predominantly in the right tumor mass, but not in the left initial and recurrent tumors (**Fig. 3c**). Different single cells harbored different *EGFR* alterations, implying that these alterations were late events during tumor evolution[21]. *PIK3CA* mutations were detected from single cells in all three samples, which is consistent with the bulk WES result that *PIK3CA* mutations are founder events (**Supplementary Figs. 1a** and **6a**). Our analysis also showed the presence of transcriptional heterogeneity within the individual samples. A subset of the left initial tumor cells was characterized by upregulation of mitotic genes that was not found in either the right or recurrent sections (**Fig. 3d**).

Additionally, we profiled *IDH1*-mutant tumor cells, which are distinguished by their 5-aminolevulinic acid (5-ALA) uptake

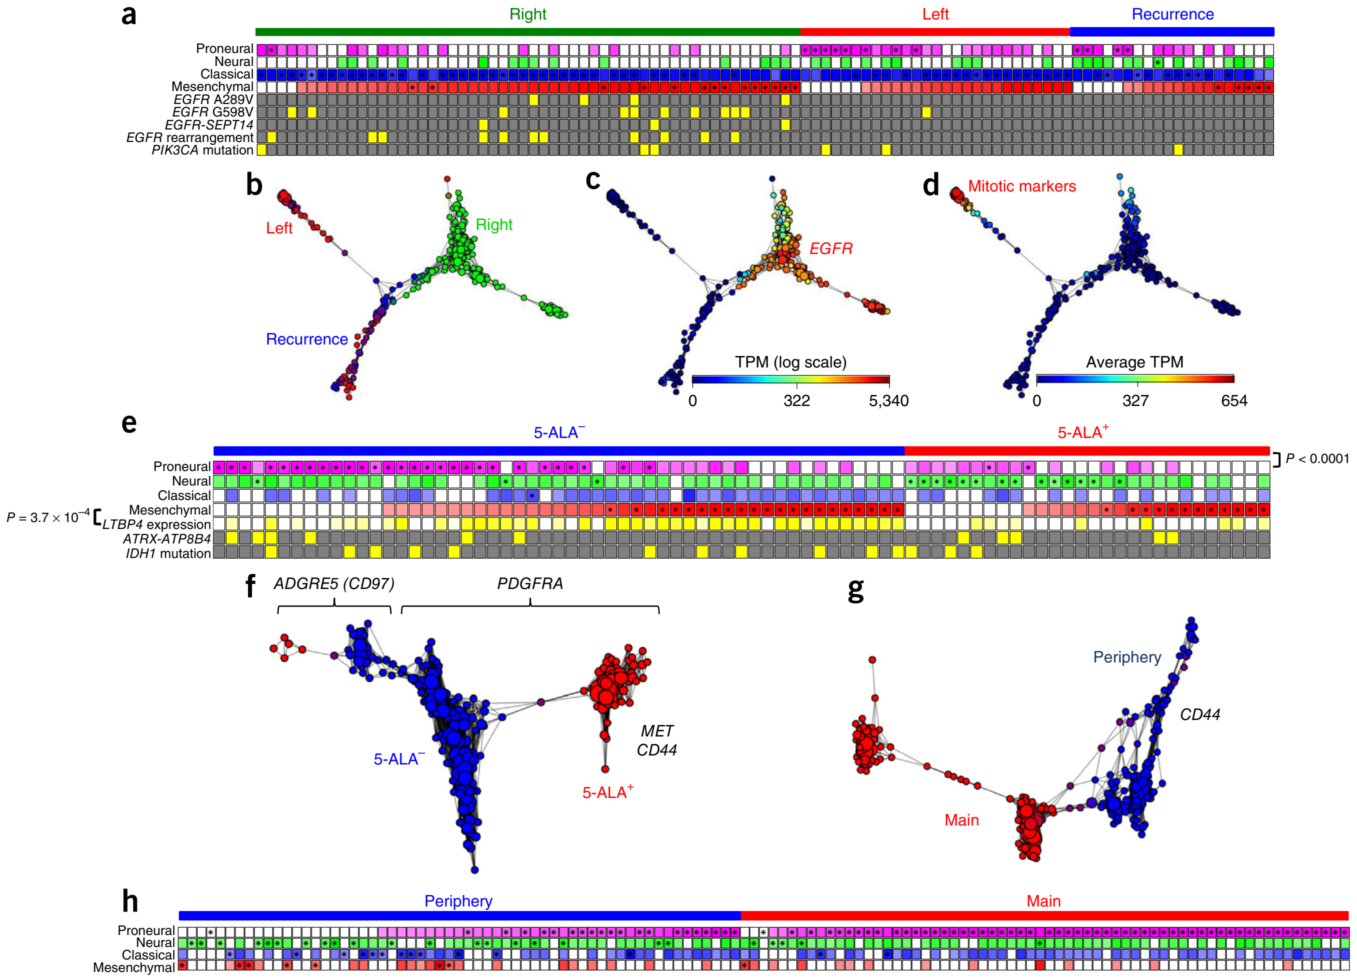

Figure 3 Single-cell transcriptomes from multiregion samples. (**a**) Expression profiles of individual tumor cells from three samples of GBM9 (left initial, right initial, and relapse) according to expression subtype[32]. For each cell, the subtype with the highest expression is marked with an asterisk. Several *EGFR* genomic alterations could be identified in the single-cell expression data (yellow), despite the abundance of missing data (gray). (**b**) Topological representation of the expression data of individual tumor cells from GBM9, labeled by sample of origin. Each node represents a set of cells with similar transcriptional profiles. A cell can appear in several nodes, and two nodes are connected by an edge if they have at least one cell in common. (**c**,**d**) Topological representations of GBM9 where tumor cells are labeled by expression of *EGFR* (**c**) and mitotic genes (**d**). TPM, transcripts per million. (**e**) Expression profiles of individual tumor cells from GBM10 (two samples: 5-ALA^{+} and 5-ALA^{-}). The *P* value for comparison of the proneural and 5-ALA profiles was obtained using Fisher's exact test. The *P* value for comparison of the mesenchymal profile and *LTBP4* expression was calculated using Spearman's correlation. *ATRX* fusion was validated by RT–PCR assays (**Supplementary Fig. 7b,c**). (**f**,**g**) Topological representations of expression data for individual tumor cells from patients GBM10 (**f**) and GBM2 (**g**), where tumors are labeled by the sample of origin. (**h**) Expression profiles of individual tumor cells from patient GBM2 shown according to GBM expression subtype. Asterisks indicate the representative subtype identities of the corresponding cells.

pattern (populations stained for tumor cellularity[24]) (GBM10; **Fig. 3e**,**f** and **Supplementary Figs. 6** and **7**). Previous glioma studies suggested that a low pathologic grade is associated with a low rate of 5-ALA uptake[24,25]; however, genomic determinants for 5-ALA uptake remain elusive. Using single-cell transcriptome analysis, we found predominant enrichment of proneural cells in the 5-ALA^{-} sample, supporting previous observations that GBM cells may evolve from proneural precursors ($P < 0.01$, Fisher's exact test; **Fig. 3e**)[26]. Also, we found enrichment of expression for several cell proliferation and migration markers in the 5-ALA^{+} section, including *MET* and *CD44* (refs. 27–29). Notably, 5-ALA^{-} tumors, which are considered to be less aggressive, are actually fully fledged tumors that harbor driver mutations and express markers for aggressive tumors (**Fig. 3e**,**f** and **Supplementary Figs. 6b**, **7**, **9a**, and **10**). Finally, we studied main tumor and resection margin samples from GBM2—a locally adjacent hypermutated case—and found distinct subpopulations of cells expressing mitotic cell markers and migration-associated genes, including *CD44* (**Fig. 3g** and **Supplementary Figs. 6**, **7**, **9**, and **10**)[28].

To investigate the influence of genetic heterogeneity on drug response, we isolated 28 PDCs from 11 individuals and screened 40 different cancer-related compounds (**Supplementary Table 5**)[4,30]. We found that Nei's genetic distance was associated with drug-response correlation ($P = 0.02$, Wilcoxon rank-sum test; **Fig. 4a**). Consistently, both distant and longitudinal samples showed significantly broader drug responses than local samples (**Fig. 4b**). We found that the PDCs from M-GBMs were more sensitive to PI3K–AKT–mTOR (PAM) pathway inhibitors than PDCs from solitary tumors were ($P = 1.872 \times 10^{-6}$, Wilcoxon rank-sum test; **Fig. 4c** and **Supplementary Fig. 11**). This indicates that PAM inhibitors could provide a clinical benefit for patients with M-GBM. In addition, we observed that PDCs from recurrent GBMs were more resistant to EGFR inhibitors than

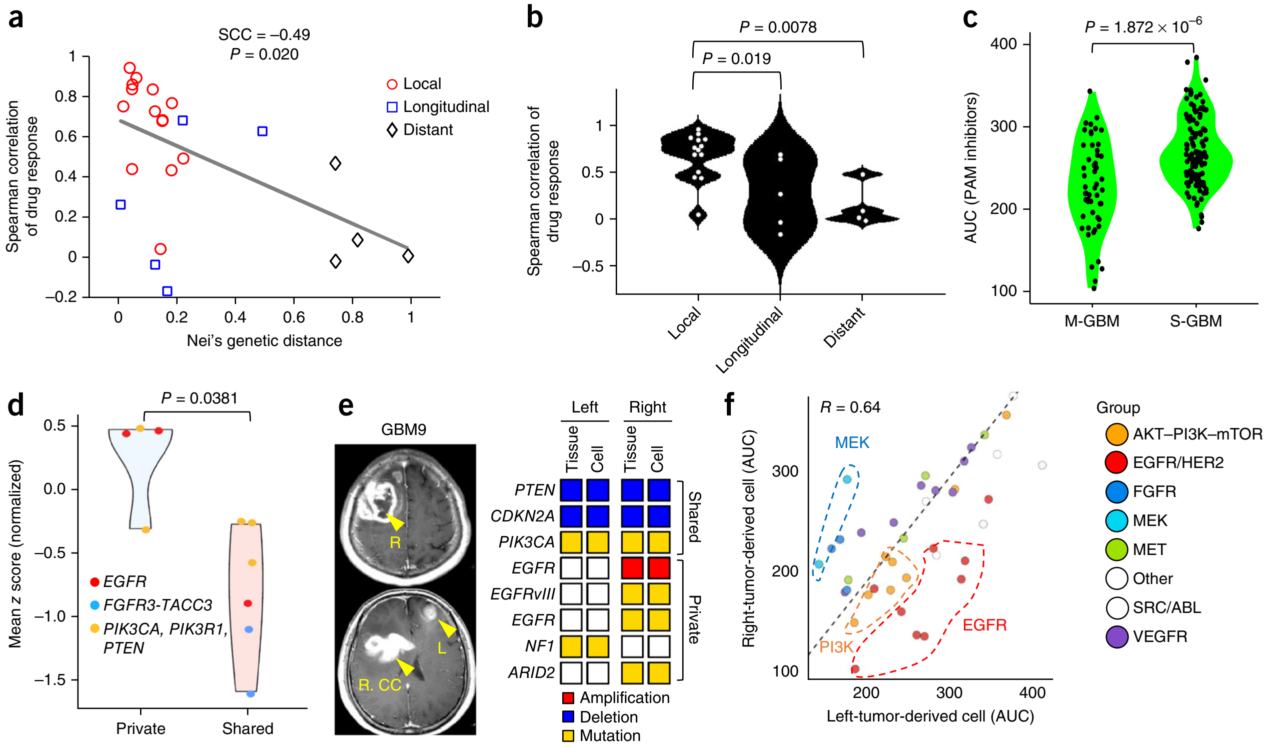

Figure 4 Chemical screening of multiregion PDCs. (**a**) PDCs were treated with 40 chemical agents targeting oncogenic signaling pathways in dilution series from 20 μM to 4.88 nM. The *x* axis shows Nei's genetic distances between fragments from the same patient, and the *y* axis shows the Spearman's correlation coefficient (SCC) of corresponding fragments based on drug sensitivities as measured by area under the curve (AUC). (**b**) Violin plots for the SCC of drug responses for the groups described in **a**. Each white dot represents a tumor sample. $n = 14$ (local), 5 (longitudinal), and 4 (distant). (**c**) Mean values of the AUCs for six PI3K–AKT–mTOR (PAM) inhibitors (BEZ235, BKM120, BYL719, AZD5363, AZD2014, and everolimus) for PDCs isolated from M-GBMs ($n = 9$) or S-GBMs ($n = 22$). Each black dot represents a mean. (**d**) The normalized *z* score for each PDC obtained from the AUCs for the indicated drug classes used in **a** and **b** was plotted when the corresponding tissues harbored associated genetic alterations, designated as 'shared' or 'private'. A genetic alteration was determined to be private when the drug-response-associated genetic alteration was private, and vice versa for the shared group. For example, *PTEN* mutations for P13K–AKT–mTOR pathway inhibitors were private, meaning they were exclusive to only one or two regions of the multisector sample. (**e**) Preoperative T1-weighted contrast-enhanced magnetic resonance images (MRIs) and key genomic alterations found in the corresponding tumors and their derivative cells for a patient with multicentric disease (GBM9). "R" indicates right-side tumors that encompassed the right frontal lobe and corpus callosum (CC). "L" indicates the left frontal lobe tumor. The preoperative MRIs show a multifocal infiltrative lesion in both the frontal lobes and CC. (**f**) Scatterplot of the AUCs for 40 cancer-targeting compounds on GBM9 PDCs that were derived from the left- and right-side tumors in the frontal lobes. Each dot represents the AUC of a given drug. The *R* value was obtained as Pearson's correlation coefficient. All *P* values in this figure were obtained using Wilcoxon rank-sum tests.

the initial tumor cells were ($P = 2.9 \times 10^{-4}$, Wilcoxon rank-sum test; **Supplementary Figs. 12** and **13**).

We hypothesized that clonal alterations found in all multisector samples (truncal alterations) represent better molecular targets than those found in only a subset of multisector samples (private alterations). In agreement with this truncal-target hypothesis (**Supplementary Video 1**), multisector PDCs were more sensitive to drugs that target shared alterations than to drugs that target private alterations ($P = 0.0381$, Wilcoxon rank-sum test; Online Methods, **Fig. 4d** and **Supplementary Figs. 14–16**). The multiverse model implies that the extensive genetic diversity of multiple tumors presents a special challenge. Accordingly, GBM9 showed a divergent genetic profile and a highly heterogeneous drug response (**Fig. 4e**,**f**). PDCs from the right-side tumor were highly sensitive to EGFR inhibitors, but not to MEK inhibitors, and vice versa for the left-side tumor. However, inhibitors of the PAM pathway were ubiquitously effective, which is consistent with our hypothesis that targeting the PAM signaling pathway could be a potent option to treat M-GBMs (**Fig. 4c**,**f**). Yet not all truncal alterations can serve as drug targets. For example, gatekeeper genes, which are necessary for tumor initiation but are no longer required for tumor maintenance, are not good candidates[31]. Although targeting subclonal mutations shows a limited effect, patients might still benefit from the elimination of a subclone that has a bystander effect on surrounding cells.

In conclusion, on the basis of comprehensive bulk and single-cell analyses, we have proposed a multiverse model to interpret the evolution of multiple GBMs. We showed that M-GBMs are more genetically diverse than locally adjacent tumors and that genetic similarity between multiregion samples is associated with consistent drug response. Specifically, we found an enrichment of *PIK3CA* mutations in M-GBMs, and we found that inhibitors of the PAM pathway are more effective in PDCs from this cohort. These findings support the truncal-target hypothesis, which states that truncal mutations can inform more effective therapies.

ONLINE METHODS

Glioma specimens and their derivative cells. After receiving informed consents, glioma specimens and clinical records were obtained from patients undergoing surgery at Samsung Medical Center (SMC) or Seoul National University Hospital (SNUH) in accordance with its institutional review board (IRB file no. 2010-04-004). Surgical samples measuring approximately 5 × 5 × 5 mm^3 were snap-frozen using liquid nitrogen for genomic analysis. We also curated whole-exome and/or RNA sequencing of 33 multisector specimens from 10 glioblastoma (GBM) patients in The Cancer Genome Atlas (TCGA) cohort[8] and 22 previously reported GBM longitudinal pairs[14,16]. To investigate the genomic characteristics of solitary and multifocal/multicentric GBMs, we curated exome sequencing data for 83 and 77 tumors with matched normal DNA from the SMC and TCGA cohorts[8,17], respectively. Portions of the surgical samples were enzymatically dissociated into single cells, following the procedures reported previously with modification of immune cell depletion[33]. Tumor cells were cultured in neurobasal medium with N2 and B27 supplements (0.5× each, half of the suggested working concentration; Invitrogen), human recombinant basic fibroblast growth factor (bFGF), and epidermal growth factor (EGF; 20 ng/ml each; R&D Systems). The patient-derived cells (PDCs) used here had shown no obvious contamination of mycoplasma.

Radiological evaluation. Both T1-weighted contrast enhancement (T1CE) and fluid-attenuated inversion recovery (FLAIR)/T2 axial images of 160 treatment-naive GBMs (83 and 77 tumors from the SMC and TCGA cohorts, respectively) were reviewed. Magnetic resonance images (MRIs) of tumors from the TCGA cohort have been obtained from The Cancer Imaging Archive (TCIA) website[17,34,35]. We excluded cases with any evidence of prior neurosurgical intervention except biopsy, lack of treatment history, or loss of T1CE or FLAIR/T2 images. To distinguish the multifocal/multicentric GBMs (M-GBMs) from solitary ones (S-GBMs), we adapted annotations from the VASARI feature set for human glioma[36]. According to the VASARI feature set, m-GBMs are defined as having at least one region of tumor, either enhancing or nonenhancing, that is not contiguous with the main lesion and is outside of the region of signal abnormality (edema) surrounding the main mass[17,37,38]. When a FLAIR/T2 high-signal-intensity lesion resides outside of the T1CR lesion, it is considered a separate tumor focus and is counted as a multifocal tumor in our study[39,40]. In contrast, tumors that present separate contrast-enhancement lesions within the FLAIR/T2 high-signal-intensity background are considered as solitary ones.

Whole-exome sequencing. An Agilent SureSelect kit was used to capture the exonic DNA fragments. An Illumina HiSeq 2000 instrument was used for sequencing and generated 2 × 101-bp paired-end reads.

Somatic mutation. The sequenced reads in the FASTQ files were aligned to the human genome assembly (hg19) using Burrows–Wheeler aligner version 0.6.2. The initial alignment BAM files were subjected to conventional preprocessing before mutation calling: sorting, removing duplicated reads, locally realigning reads around potential small indels, and recalibrating base quality scores using SAMtools, Picard version 1.73, and Genome Analysis Toolkit (GATK) version 2.5.2. We used MuTect (version 1.1.4) and Somatic IndelDetector (GATK version 2.2) to make high-confidence predictions on somatic mutations from the neoplastic and non-neoplastic tissue pairs. Variant Effect Predictor (VEP) version 73 was used to annotate the called somatic mutations. Additionally, we ran SAVI (Statistical Variant Identification) software to call somatic variants and indels in order to for refine the mutation calls from the above pipeline.

Copy number. Excavator was used to generate estimated copy number alterations in a tumor specimen in comparison with its matching, non-neoplastic part. For each gene, we calculated copy number = 2^{x+1}, where x is the segmentation mean from Excavator, which is defined as the $\log_2$ (fold change) in the tumor divided by the normal sample. The gene was labeled as 'amplified' when the copy number was 3 and 'deleted' when it was ≤1.

Cancer cell fractions and clonality. We ran ABSOLUTE[41] using input of genomic variants and copy number data to infer sample purity and cancer cell fractions (CCFs) and removed those that had <20% purity. We considered mutations as clonal if they were indicated as clonal in ABSOLUTE and had a CCF of at least 80% or if they had a CCF of 100% and were not marked as clonal or subclonal. The ABSOLUTE CCF estimates with regard to hypermutated samples appeared disproportionately subclonal in sample GBM18 initial and in TCGA-14-1402 second recurrence; we reasoned that the large mutational load might skew estimates. In hypermutated samples, treatment-associated mutation coupled with defects in mismatch repair is deemed largely responsible for a majority of observed mutations. Therefore, mutations having CCFs greater than or equal to the maximum mismatch repair CCF were marked clonal in these two samples.

If a mutation was found to be clonal in all sectors of a patient's tumor, it was inferred to be clonal throughout the entire tumor. We investigated the number of sequenced tumor sectors or cores needed to obtain a reasonable false discovery rate (FDR) for this inference of clonality. We analyzed glioma patient LGG174, published recently by Suzuki *et al.*, where nine sectors from different locations of the same tumor mass were sequenced[42]. On the basis of Figure 7b from that paper[42], 13 mutations have a high tumor cell fraction (>60%) shared by all samples. To relate the number of sectors that were sequenced to the number of mutations deemed to be clonal tumor-wide, we exhausted all possible subsampling strategies (number of cores $k = 1, 2, \ldots, 9$) and calculated the reported clonal mutations based on k cores. For example, if there are two cores ($k = 2$), there are $C_2^9 = 36$ potential sampling strategies. We found that 22 of 36 sampling strategies contained no false discoveries in identifying clonal mutation. For each value of k, we calculated the FDR (**Supplementary Fig. 17**). Almost 90% of clonal mutations identified by two-core sequencing are true clonal mutations, and over 95% identified by three-core sequencing are true clonal mutations.

Nei's genetic distances. Nei's genetic distance is used in population genetics to assess the similarity between populations, taking into account heterogeneity within populations. Samples containing the same spatial or longitudinal category (local, 5-ALA, multiple lesion, longitudinal local, longitudinal distant) were retained for statistical comparisons. We calculated Nei's genetic distance of CCF for each patient's sample as follows. Let x be all CCFs of sample 1 and y be all CCFs of sample 2.

$$D = -\log \frac{\sum(x_i y_i + (1 - x_i)(1 - y_i))}{\sqrt{(\sum x_i^2 + (1 - x_i)^2)(\sum y_i^2 + 1 - y_i)^2)}}$$

The multiverse model of tumor evolution. We found an increased Nei's genetic distance in multifocal/multicentric biopsies when compared with those that were locally adjacent. In addition, private clonal mutations appear frequently in multisectional and distant longitudinal samples, but are infrequent in local samples (**Supplementary Fig. 2a**). This spurred a hypothesis that specific early event(s) can give rise to distinct mutational profiles in spatially separated tumors (**Fig. 2a**). These differences in mutational load suggested that distinct tumor profiles might arise in separate 'universes' of clones rather than from one large growth period followed by diversification.

For each somatic mutation, we recorded the clonal status as determined by ABSOLUTE and whether the mutation is shared or private, or the clonal status changed between biopsies. Mutations are then classified into five patterns with respect to every available pair of a patient's samples. The mutational classes were labeled as the following: CC (clonal–clonal), CS (clonal–subclonal), SS (subclonal–subclonal), CX (clonal–absent), or SX (subclonal–absent). The order of the sample pair was not important: a mutation that was clonal in one sample and subclonal in the other was marked "CS," regardless of sample identity.

These mutational classifications were used to predict whether the spatiotemporal configuration of a sample pair fell into one of three groups: locally adjacent, local longitudinal, or multisectional/distant longitudinal. The fractions of mutations in a sample pair that fit each of the five patterns were used as features in a multinomial logistic regression. Predictions were then made using leave-one-out cross-validation.

Mutational pairs plotted on the simplex allowed us to visually separate multisectional/distant longitudinal, locally adjacent, or local longitudinal sections in agreement with most of our MRI classifications. The simplex

© 2017 Nature America, Inc., part of Springer Nature. All rights reserved.

axes represent the predicted probabilities of outcomes for each observation. The sample layout contained three local longitudinal outliers closest to the multisectional point of the simplex. The time interval between surgeries for the three pairs was 18 months or more. Moreover, their Nei distances were significantly different from all other sections ($P = 0.01652$). We labeled all samples exceeding surgical intervals of 18 months as long-term recurrence and colored them in dark green. Analysis was performed in the R computing environment using the multinom function from the nnet package (see "Data availability").

Isolation of single cells and RNA sequencing. We adopted the C1TM Single-Cell Auto Prep System (Fluidigm) with the SMARTer kit (Clontech) to generate cDNAs from single cells. Cells were captured as a single isolate on a C1 chip (17–25 μm), as determined from bright-field images obtained under 100× magnification using an Axiovert200 inverted microscope (Carl Zeiss). RNAs from pooled samples were also processed using the SMARTer kit with 10 ng of starting materials. Libraries were generated using the Nextera XT DNA Sample Prep Kit (Illumina) and sequenced on the HiSeq 2500 using the 100-bp paired-end mode of the TruSeq Rapid PE Cluster kit and TruSeq Rapid SBS kit. Before mapping RNA sequencing reads to the reference, reads were filtered out at Q33 by using Trimmomatic-0.30. Transcripts per million (TPM) values were calculated from each single cell (as if they were different samples) using RSEM (version 1.2.25)[43] and are expressed as $\log_2$ (1 + TPM).

Gene fusion detection. Chimerascan was applied to generate a list of candidate gene fusions[44]. For bulk sequencing, only previously reported in-frame, highly expressed fusions, such as *FGFR3-TACC3* (ref. 18), *MGMT* fusion[14], *EGFR-SEPT14* (ref. 5) and *ATRX* fusion, were considered in this manuscript. For single-cell fusion analysis, if a fusion was highly expressed and independently detected in multiple cells, the fusion was reported.

Expression-based subtype determination. Gene expression was measured by RSEM and then $\log_2$ transformed. To determine the expression-based subtype of GBM cells, we first calculated z scores for gene expression data across samples and then applied ssGSEA (version gsea2-2.2.1) to the normalized expression profile. For each cell, we ranked all genes on the basis of their expression values to create a .rnk file as input for the software GseaPreranked. An enrichment score was computed for all four subtypes initially defined in Verhaak *et al.*[32]. The subtype with the maximal enrichment score was used as the representative subtype for each cell.

Topological data analysis using single-cell transcriptomes. We filtered out normal cells on the basis of their expression profile. To that end, we considered the expression signatures of normal oligodendrocytes, neurons, astrocytes[45], microglia[46], endothelial cells[47], T cells[48], and other immune cells[48,49], and we used a Gaussian mixture model to classify individual cells according to their expression profile. 94/133, 82/85, and 90/137 cells for GBM9, GBM10, and GBM2, respectively, were classified as tumor cells. After normalizing the gene expression level by dividing by the total number of reads in each cell to eliminate potential bias caused by batch effect, we built topological representations of these single-cell data using the Mapper algorithm[23], as implemented by Ayasdi. Open-source implementations of this algorithm are also available (see "Data availability"). We used the first two components of multidimensional scaling (MDS) as auxiliary functions for the algorithm. The output of Mapper is a low-dimensional network representation of the data, where nodes represent sets of cells with similar global transcriptional profiles (as measured by correlation of the expression levels of the 2,000 genes with the highest variance across each patient). We identified individual genes that had an expression pattern localized in the network and used these to determine the subclonal structure of the samples at the level of expression.

PDC-based chemical screening and analysis. PDCs grown in serum-free medium were seeded in 384-well plates at a density of 500 cells per well in duplicate or triplicate for each treatment. The drug panel consisted of 40 anticancer agents (Selleckchem) targeting oncogenic signals. Two hours after plating, PDCs were treated with drugs in a fourfold and seven-point serial dilution series from 20 μM to 4.88 nM using the Janus Automated Workstation (PerkinElmer). After 6 d of incubation at 37 °C in a 5% CO_2 humidified incubator, cell viability was analyzed using an ATP-monitoring system based on firefly luciferase (ATPLit 1step, PerkinElmer). The number of viable cells was estimated using the EnVision Multilabel Reader (PerkinElmer). DMSO was also included as a control in each plate. Controls were used for the calculation of relative cell viability for each plate, and normalization was performed on a per-plate basis. Dose-response curve (DRC) fitting was performed using GraphPad Prism 5 (GraphPad) and evaluated by measuring the area under the curve (AUC) of the DRC. After normalization, best-fit lines were determined and the AUC value of each curve was calculated using GraphPad Prism, ignoring regions defined by fewer than two peaks.

Cell viability was determined via calculating AUC values of DRCs with exclusion of nonconvergent fits[50].

Moduli space analysis. To illustrate the evolution histories of tumors in GBM patients, we applied moduli space analysis[51] in local and multiple groups of patients. Multiregion pairs were compared to calculate the number of shared and private mutations. In this analysis, clonal mutations were separated on the basis of their allele frequencies. Sector pairs were put in the left sphere on the basis of the number of shared and private mutations with high-allele-frequency mutations (>20%), whereas the same number of pairs were put in the right sphere on the basis of mutations with low-allele-frequency mutations (<20%). The same analysis was repeated using CCF instead of mutational allele fraction.

Immunohistochemistry. Tissue specimens were fixed by formalin and embedded in paraffin. Paraffin-embedded sections were treated with 0.3% hydrogen peroxide to block endogenous peroxidase activity, and antigens were retrieved by heating sections in 10 mM sodium citrate (pH 6.0) at 95 °C for 30 min. Sections were incubated with primary antibodies overnight at 4 °C, biotinylated secondary antibodies for 1 h at room temperature, and avidin–biotin complex for 1 h at room temperature.

Protein blotting. GBM PDCs were washed with cold PBS and harvested in lysis buffer (150 mM sodium chloride, 1% Triton X-100, 1% sodium deoxycholate, 0.1% SDS, 50 mM Tris-HCl, and 2 mM EDTA), and a protease and phosphatase inhibitor cocktail was added (Thermo Scientific). Insoluble materials were removed by centrifugation at 13,500*g* for 15 min at 4 °C. Proteins were separated by SDS–PAGE. Immunoblotting was performed using antibodies against indicated proteins.

Limiting dilution assays. GBM PDCs were dissociated into single-cell suspensions and then plated into 96-well plates at 1–250 cells per well. Cells were incubated at 37 °C for 1–2 weeks. At the time of quantification, each well was examined for formation of neurosphere-like cell aggregates. Statistical significance was evaluated using extreme limiting dilution analysis (ELDA; Walter+Eliza Hall Bioinformatics).

Gene fusion validation. Validation of gene fusion transcripts were performed by RT–PCR assays. Total RNA was extracted from tissues by AllPrep DNA/RNA Mini Kit according to the manufacturer's instructions (Qiagen). Total RNA (1 μg) was reverse transcribed to synthesize template cDNA by random hexamers using the SuperScript III First-Strand System (Life Technologies), and 20 μl of synthesized cDNA was diluted fivefold with DEPC-treated water. For RT–PCR, EzWay Taq PCR MasterMix (Komabiotech, Korea) and 5 μl of synthesized cDNA template were used. Thermal cycling was carried out under the following conditions: incubation at 95 °C for 1 min followed by 30 cycles of 30 s at 95 °C, 30 s at 56 °C, and 30 s at 72 °C. The primer pairs used in this experiment were designed to generate the amplification product, including the breakpoints of the fusion genes. PCR products were analyzed by agarose gel electrophoresis. The primers are summarized in **Supplementary Table 6**.

Abstract

There is a great deal of hype surrounding the concept of 'personalized' medicine. Personalized medicine is rooted in the belief that since individuals possess nuanced and unique characteristics at the molecular, physiological, environmental exposure and behavioral levels, they may need to have interventions provided to them for diseases they possess that are tailored to these nuanced and unique characteristics. This belief has been verified to some degree through the application of emerging technologies such as DNA sequencing, proteomics, imaging protocols, and wireless health monitoring devices, which have revealed great inter-individual variation in disease processes. In this review, we consider the motivation for personalized medicine, its historical precedents, the emerging technologies that are enabling it, some recent experiences including successes and setbacks, ways of vetting and deploying personalized medicines, and future directions, including potential ways of treating individuals with fertility and sterility issues. We also consider current limitations of personalized medicine. We ultimately argue that since aspects of personalized medicine are rooted in biological realities, personalized medicine practices in certain contexts are likely to be an inevitability, especially as relevant assays and deployment strategies become more efficient and cost-effective.

Introduction

The application of emerging, high-throughput, data-intensive biomedical assays, such as DNA sequencing, proteomics, imaging protocols, and wireless monitoring devices, has revealed a great deal of inter-individual variation with respect to the effects of, and mechanisms and factors that contribute to, disease processes. This has raised questions about

the degree to which this inter-individual variation should impact decisions about the optimal way to treat, monitor, or prevent a disease for an individual. In fact, it is now widely believed that the underlying heterogeneity of many disease processes suggests that strategies for treating an individual with a disease, and possibly monitoring or preventing that disease, must be tailored or ‘personalized’ to that individual's unique biochemical, physiological, environmental exposure, and behavioral profile. A number of excellent reviews on personalized medicine have been written, including a growing number of textbooks on the subject meant for medical students and clinicians. It should be noted that although many use the term ‘personalized’ medicine interchangeably with the terms ‘individualized’ and ‘precision’ medicine (as we do here), many have argued that there are some important, though often subtle, distinctions between them.(1, 2))

There are a number of challenges associated with personalized medicines, especially with respect to obtaining their approval for routine use from various regulatory agencies. In addition, there have many issues associated with the broad acceptance of personalized medicines on the part of different health care stakeholders, such as physicians, health care executives, insurance companies, and, ultimately, patients. Almost all of these challenges revolve around a need to prove that personalized medicine strategies simply outperform traditional medicine strategies, especially since many tailored or personalized therapies, such as autologous CAR-T cell transplant therapies for certain types of cancer(3) and mutation-specific medicines such as ivacaftor to treat cystic fibrosis (4, 5), can be very expensive(6). In this review we consider the history and motivation of personalized medicine and provide some context on what personalized medicines strategies have emerged in the last few decades, what limitations are slowing their advance, and what is on the horizon. We also consider strategies for proving that personalized medicine protocols and strategies can outperform traditional medicine protocols and strategies. Importantly, we distinguish examples and challenges associated with personalized disease prevention, personalized health monitoring, and personalized treatment of overt disease.

Archibald Garrod and The Precursors Of Personalized Medicine

There is much in the history of western medicine that anticipates the emergence of personalized medicine. For reasons of brevity, we will not focus on all of these events, but rather only a few that we feel encompass the most basic themes behind personalized medicine. More than a century ago Archibald Garrod, an English physician, began studying in earnest diseases that would later become known as ‘inborn errors of metabolism.’ Garrod studied a number of rare diseases with overt, visible phenotypic manifestations including alkaptonuria, albinism, cystinuria and pentosuria. Of these, his focused work on alkaptonuria led to some notoriety when he observed that some members of families exhibiting alkaptonuria showed measurably outlying values for certain basic biochemical assays, e.g., from urine, relative to the values of family members who did not possess alkaptonuria. This led him to conclude that alkaptonuria was due to a specific ‘altered course of metabolism’ among affected individuals, which was subsequently proven correct.(7) Further, in considering other rare diseases like alkaptonuria, Garrod argued that “…the thought naturally presents itself that these [conditions] are merely extreme examples of variation of chemical behavior which are probably everywhere present in minor degrees and that just as

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

no two individuals of a species are absolutely identical in bodily structure neither are their chemical processes carried out on exactly the same lines”. This more than hints at his belief that, at least with respect to metabolism, humans vary widely and that these differences in metabolism could help explain overt phenotypic differences between individuals, such as their varying susceptibilities to diseases and the ways in which they manifest diseases.(8, 9)

Garrod was working in the backdrop of a great deal of debate about the emerging field of genetics. Although the specific entities we now routinely refer to as genes (i.e., stretches of DNA sequence that code for a protein and related regulatory elements), were unknown to Garrod and his contemporaries, he and others often referred to ‘factors’ influencing disease possessed by certain individuals that were consistent with the modern notion of genes. Claims about the very presence of such factors were born out of discussions rooted in the findings of Mendel (later, it would be shown that many of the metabolic outliers Garrod observed in people with diseases like alkaptonuria were due to defects in genes possessed by people with those diseases). Mendel observed consistent connections between the emergence of very specific phenotypes only when certain breeding protocols were followed in peas that anticipated the modern field of genetics.(10) Essentially, as discussed in an excellent book by William Provine,(11) many in the research community at the time debated how genes or factors of the type Garrod and others were considering could explain the broad variation in phenotypic expression observed in nature. One group of academics and researchers, referred to as the ‘Mendelians’ in the historical literature, which included William Bateson and Hugo de Vries, focused on the discrete nature of the factors likely to be responsible for many observable inheritance patterns (such as those of focus in Mendel's studies and observations like Garrod's in the context of rare disease). In opposition to the ‘Mendelians’ were the ‘Biometricians,’ represented most notably by Karl Pearson, whose focus on continuous or graded phenotypes, like height, gave them concerns about how to reconcile such continuous variation with the overtly discrete (‘either/or’) factors and inheritance patterns considered by the Mendelians and researchers like Garrod.

The Mendelian vs. Biometrician debate was resolved to a great extent by the statistician Ronald Fisher in a series of seminal papers. Fisher argued that one could reconcile continuous phenotypic variation with discrete, heritable factors that contribute to this variation by suggesting that many factors (i.e., genes) might contribute in a small way to a particular phenotype. The collective effect, or sum total, of these factors could then create variation in phenotypes that give the appearance of continuity in the population at large (e.g., an individual who inherited only 1 of 25 genetic variants known to increase height would be shorter on average than someone who inherited 10 or 12, and much shorter, relatively speaking, than an individual who inherited 22 or 25).(12) The belief that there might be many genes that contribute to phenotypic expression broadly, some with more pronounced effects and some with less pronounced effects, that interact and collectively contribute to a phenotype in a myriad of ways, has been validated through the application of modern high-throughput genetic technologies such as genotyping chips and DNA sequencing. As a result, much of the contemporary focus on personalized medicine is rooted in the findings of genetic studies, as it has been shown that individuals do in fact vary widely as each individual possesses subsets of literally many millions of genetic variants that exist in the human population as a whole. In addition, subsets of these genetic variants may have arisen

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

as *de novo* mutations and hence may be unique to an individual. These extreme genetic variation explains, in part, why individuals vary so much with respect to phenotypes, in particular their susceptibilities to disease and their responses to interventions.(13) It should be emphasized that although personalized medicine has its roots in the results of genetic studies, it is widely accepted that other factors, e.g., environmental exposures, developmental phenomena and epigenetic changes, and behaviors, all need to be taken into account when determining the optimal way to treat an individual patient (see Figure 1).(14-16)

Another, sadly more obscure, publication was also prescient for personalized medicine, although this publication bears more on the need for clinical practices that are consistent with personalized medicine – rather than a scientific justification of personalized medicine. More than 60 years ago Hogben and Sim considered how clinical practice needs to pay attention to nuanced characteristics of patients in order to determine an appropriate intervention for them.(17-19) Although more will be discussed about their paper in the section on ‘Testing Personalized Medicines,’ suffice it to say that the authors believed that in order to determine an optimal course of action for an individual patient in the absence of any *a priori* understanding of how best to treat that patient given his or her characteristics or profile, a number of items would need to be obtained. Thus, greater information about that patient would have to be gathered, a plan to vet the utility of an intervention chosen on the basis of that information would have to be pursued, and a strategy for incorporating the results of the patient-oriented study into future care would have to be crafted. Although simple in theory, the practical issues surrounding gathering more information about a patient and pursuing an the empirical assessment of a personalized intervention can be daunting. For example, questions surrounding how one can know that a chosen intervention works unless meticulous patient follow-up information is kept, how one would know if a patient satisfied with what they are experiencing with the intervention, and how one could assess the difference between other interventions that could have been chosen and the chosen personalized intervention, would all need to be addressed. In fact, practical issues surrounding the implementation of personalized medicine that Hogben and Sim considered are often overlooked in contemporary discussions about personalized medicine, especially since different technologies for profiling patients are constantly being developed and refined, and more and more evidence for inter-individual variation in factors associated with diseases (from technologies such as DNA sequencing, proteomics, sophisticated imaging protocols, etc.) is emerging.

Early Examples of Personalized Medicine

There have been a great many examples of interventions tailored to individual patient profiles, virtually all of them based on genetic profiles. Before providing a few classic examples, it should be emphasized that personalized medicine can be practiced not only for the treatment of disease, but also for the early detection and prevention of disease. We provide some historical examples of personalized disease treatments here and consider early detection and prevention in the next section, as developments in personalized disease detection and prevention are much more recent.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

The human body deals with traditional pharmacotherapies (i.e., drugs) to treat disease in two general ways. Initially, the body must respond to a drug. This response occurs in steps, with the first step involving the absorption of the drug by the body. The drug must then be distributed throughout the body (during this process the drug might be ‘biotransformed’ or metabolized into useful components) and then begin to elicit effects. Finally, any remaining drug or drug components are excreted. These processes are often lumped under the heading of ‘pharmacokinetics’ and collectively referred to as the ‘ADME’ of a drug (Absorption, Distribution, Metabolism and Excretion). Pharmacokinetic activity is often under the control of a unique set of genes (e.g., drug metabolizing enzymes) that could harbor naturally-occurring genetic variants (or ‘polymorphisms’) that influence their function and hence how the body ultimately deals with a particular drug. Once a drug is within the body, how it interacts with its target (typically a gene or protein encoded by a gene) to elicit an effect is known as its ‘pharmacodynamic’ properties. These properties include the ‘affinity’ the drug has for its target(s), the drug's ability to modulate the target(s) (or its ‘efficacy’), and the ‘potency’ of the drug, or how much of the drug is needed to induce a certain change in its target. Pharmacodynamic properties of a drug are also under genetic control.

Many early examples of personalized medicines were associated with genetically-mediated pharmacokinetic aspects of drugs. This was due in part to the biomedical science community's understanding of drug metabolizing enzymes and the role they play in the body's response to drugs. An excellent introduction to pharmacogenetic properties of drugs, as well genetic variants in genes that influence the efficacy and side effects of drugs (especially with respect to genetic variants in drug metabolizing enzymes) is the book by Weber.(20) Warfarin is a widely used blood thinning medication that, if not dosed properly, could cause a potentially life-threatening adverse drug reaction. Warfarin targets a particular gene, VKORC1, and is metabolized in part by the gene CYP2C9. Naturally-occurring genetic variation in both the VKORC1 and CYP2C9 genes leads to variation in the pharmacodynamic and pharmacokinetic properties of Warfarin across individuals, ultimately creating variation in individuals' responses to warfarin. The US Food and Drug Administration has therefore recommended that dosing for warfarin take into consideration an individual's genotype (i.e., the dose must be personalized to an individual based on the specific genetic variants they possess in the VKORC1 and CYP2C9 genes).(21)

Another classic example of a drug that should only be provided to individuals with a certain genetic profile is primaquine (PQ). PQ has been used to manage malaria with some success in parts of the world where malaria is endemic. However, military doctors working in the past observed that some of the soldiers they treated for malaria that were provided the drug became jaundiced and anemic, and ultimately exhibited symptoms of what would later be termed ‘acute haemolytic anaemia (AHA)’. It was later shown that the individuals exhibiting AHA after PQ administration carried variants in the G6PD gene.(22) Current clinical practice with PQ therefore calls for the genotyping of individual patients to see if they carry relevant variants in the G6PD gene that might discourage PQ use for them.

A final, often-cited example of a personalized medicine is the drug imatinib.(23) Imatinib is used to treat chronic myelogenous leukemia (CML). Imatinib inhibits an enzyme, tyrosine kinase, that is increased by the formation of a fusion of two genomic regions, one

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

encompassing the Abelson proto-oncogene (abl) and the other the breakpoint cluster region (bcr). This fusion event arises in many tumors contributing to the development of CML and is referred to as the ‘bcr-abl fusion’ or ‘Philadelphia chromosome.’ However, not all individuals with CML have tumors harboring the bcr-abl fusion mutation. Therefore, imatinib is typically given only to individual CML patients with this fusion event.

Contemporary Examples Of Personalized Medicine

Drugs like warfarin, PQ and imatinib that appear to only work – or only work without side effects – when a patient possesses a certain genetic profile, have generated tremendous interest in identifying factors, such as genetic variants, that influence an individual patient's response to any number of drugs and interventions. This interest in crafting personalized medicines to treat diseases has expanded into personalized disease surveillance (i.e., early detection protocols) and personalized disease prevention strategies as well. We briefly describe a few very recent examples of this activity.

Mutation-Specific Therapies

Instead of developing a drug and then identifying factors that mitigate its efficacy or side effects through observational studies on individuals provided the drug, as with warfarin, PQ and imatinib, there are now attempts to identify, e.g., genetic profiles possessed by patients and then craft therapies that uniquely target those profiles. For example, the drug ivacaftor mentioned earlier was designed to treat individuals with cystic fibrosis (CF) that have very specific pathogenic mutations in the gene CFTR.(4) The CFTR gene has many functions, but one set of functions is dictated by a ‘gate-like’ structure in the CFTR gene's encoded protein that can open and close to control the movement of salts in and out of cells. If the CFTR gene is dysfunctional, then the gate is closed, causing a build-up of mucus and other material in the lungs. Different mutations in the CFTR gene cause different types of dysfunction. For example, some mutations simply cause the CFTR gene to not produce anything, whether the gate is open or not. Other mutations cause the gate mechanism to dysfunction. Ivacaftor is designed to open the gate for longer periods of time in the presence of certain mutations that tend to cause the gate to be closed. Therefore, ivacaftor is only useful for the small subset of CF patients whose CFTR mutations lead to this specific gating problem. Connections between genetic variants and drug efficacy and side effects are growing in number, and in fact the US FDA provides a list of approved drug-based interventions that require a test to determine their appropriateness for an individual: https://www.fda.gov/Drugs/ScienceResearch/ucm572698.htm. Other publications consider the practical implications of approved personalized medicine interventions, such as the report produced by the Personalized Medicine Coalition (PMC).(24)

A second example involves the emerging set of cancer treatments known as immunotherapies.(25) Although there are many types of immunotherapies, all of them seek to prime or trigger an individual's own immune system to attack a cancer. One type of immunotherapy exploits potentially unique sets of genetic alterations that arise in a cancer patient's tumor cells, known as ‘neo-antigens,’ which are often capable of raising an immune response if recognized properly by the host's immune cells. Essentially, this type of

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

immunotherapy works by harvesting cells from a patient that mediate that patient's immune reactions, such as T cells, then modifying those cells to specifically recognize and target the neo-antigens found to be present in the patient's tumor. These modified cells are then put back in the patient's body so these cells can attack the tumor cells giving off the neo-antigen signals. Cytotoxic T cell therapies like this, as well as immunotherapies in general, have had notable successes, but can be very patient-specific for two reasons. First, the neo-antigen profile of a patient might be very unique, such that cytotoxic T cells made to recognize and attack a specific set of neo-antigens will not work in someone whose tumor does not have those neo-antigens. Second, if ‘autologous’ constructs are used, then the patient's own T cells are modified, and hence not likely to work as well in another patient, although attempts to make ‘allogeneic’ constructs in which one individual's T cells are modified and introduced into another patient's body are being pursued aggressively.(25)

Personalizing Early Detection Strategies

If an individual is susceptible to a disease, or susceptible to recurrence of a disease, then that individual should be monitored. It is now believed that such monitoring should be pursued with use of ‘personal thresholds,’ as opposed to ‘population thresholds,’ to make claims about evidence or signs of disease or a pathogenic process.(26) Population thresholds are derived from epidemiologic data and population surveys and include, for example, cholesterol levels > 200 being an indicator for risk of heart disease, or systolic blood pressure > 140 being an indicator of hypertension, risk of stroke or heart disease. Personal thresholds are established from legacy values of a measure collected on an individual over time that used to gauge how deviant future values of that measure might be for that individual. Significant deviations from historical or average legacy values are taken as a sign of a health status change, irrespective of whether or not those values are beyond a population threshold.(27) As an example, Drescher et al.(26) explored the utility of personal thresholds applied to longitudinal CA125 levels collected on a number of women, a subset of whom developed ovarian cancer. The authors found that in all but one instance, the application of personal thresholds would have captured the presence of ovarian cancer at the same time as, or importantly earlier than, the application of population thresholds. Further, the authors showed that the use of personal thresholds could have captured the ovarian cancer almost a year earlier, on average, then the use of population thresholds. As the costs and convenience associated with monitoring assays and technologies improves (i.e., they become cheap and non-intrusive, if not transparent, to an individual user, say through an easily implantable wireless device), then the use of personal thresholds will likely become the rule rather than the exception in health monitoring protocols.

Personalizing Disease Prevention

The use of genetic information to develop personalized disease prevention strategies is now well established in the scientific community, but not yet widely adopted in clinical practice. There are many excellent examples of how the use of genetic information can lead to both a decreased risk of disease development as well as decreased complications from standard treatment and screening strategies. A prime example relates to colorectal cancer, which remains the third leading cause of cancer deaths despite being a highly preventable illness. In 2012 Liao et al. reported an improvement in overall survival and a decreased risk for

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

cancer-specific deaths in patients taking postoperative aspirin if they exhibited a somatic mutation in the PIK3CA gene in their colorectal cancers compared with patients whose cancers had the wild-type PIK3CA gene.(28) In 2015, Nan et al. reported varying effects of aspirin use on risk for development of colorectal cancer depending on an individual's genotype, with individuals possessing different genotypes having either lower, higher or no change in their risk of colorectal cancer development with aspirin use.(29) Given that aspirin use can have serious side effects associated with intestinal and intracranial bleeding, it would be ideal to limit the use of this medication for those individuals predicted to have a side effect, based on genotype.

As another example, in 2018, Jeon et al. reported the use of expanded risk prediction models for determining when to begin colorectal cancer screening. Currently the guidelines use only age and family history as variables. Jeon et al. showed that by using information about an individual's environmental exposure and genetic profile, specifically the presence of colorectal cancer associated genetic variants, recommendations for when to start screening could change by 12 years for men and 14 years for women.(30) The accuracy of relevant predictions about an individual's risk for colorectal cancer has been studied and suggests that the area under the curve (AUC) value for a model including environmental and genetic factors, where an AUC of 1.0 would suggest a model with perfect predictive accuracy, was 0.63 for men and 0.62 for women. This is compared to an AUC value of 0.53 (men) 0.54 (women) when only family history information was considered. Although there is still room for improvement given the AUCs were only ~0.62 for the model with patient environmental exposure and genetic information, the considerable improvement over models that did not include genetic or environmental information justifies their use.

Testing Personalized Medicines

Although we have argued that personalized medicine is rooted in a great number of legacy insights and historical precedents, mostly related to genetics and rare diseases, its recognition as a paradigm that should be embraced broadly by the biomedical research and clinical communities is relatively recent. This suggests that not enough time has elapsed since the time of this recognition for researchers to show that personalized medicine actually works in a wide enough variety of settings to motivate its broad adoption. In this light, questions of how the community can vet or test the utility of personalized medicine arise. We describe three emerging strategies for vetting personalized medicines below, including N-of-1 clinical trials, intervention-matching trials, and adaptive clinical trials, and argue that although these strategies borrow elements from traditional randomized clinical trials (RCTs), they deviate significantly from historical population-based RCTs that were prominent in the past.

N-of-1 Clinical Trials

If there is no reason to believe that any one of a set of different interventions matches an individual's profile (e.g., genomic, behavioral, etc.) better than others, then there is ‘equipoise’ among those interventions. In this case it becomes an empirical question as to which intervention might be optimal for the individual in question. Trials focusing on an

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

individual's response to different interventions to determine an optimal intervention are referred to as ‘N-of-1’ or single subject trials. N-of-1 trials often exploit a simple cross-over design or even a repeated crossover designs, such as ‘ABABAB’ designs, where ‘A’ and ‘B’ refer to different interventions, and the sequence ‘ABABAB’ refers to the order in which the interventions are provided to a patient. Alternating interventions, and collecting data on the individual's response to those interventions, allows comparisons of those interventions (for example between a test intervention and a comparator, or placebo, intervention. Randomization, blinding, washout periods, multiple endpoints, and many other design elements can be used in N-of-1 trials.(27, 31, 32)

N-of-1 trials involving the provision of different interventions in sequence to an individual and evaluating outcomes for each, need to accommodate serial correlation between the observations, as well as possible carry-over effects from one intervention to another, but these issues can largely be overcome with appropriate analytical methods and study design.(32) Cross-over based N-of-1 trials are impractical, if not unethical, in settings where an individual is suffering from an acute or life-threatening condition, since switching from one intervention to another may exacerbate that individual's condition. However, sequential N-of-1 designs, in which measures are continuously monitored in real time to determine if an intervention is causing harm or working, have been proposed for these situations.(27) Given that the focus of an N-of-1 trial is on the identification of an optimal intervention for an individual, rather than on the average response to an intervention in the population at large (which is often the focus of traditional RCTs), they may be most appropriate to conduct in actual clinical practice when a physician is faced with equipoise, as considered by Hogen and Sim.(33, 34)

Intervention Matching Trials

If evidence is found that certain features in individual patients' profiles can be used to identify interventions that might work for each of them, then a question arises as to how to test that the hypothesis that providing interventions to those individuals based on these ‘matches’ leads to better outcomes than providing those individuals interventions based on some other scheme or strategy. One could test each individual match, but this may require pursuing many small clinical trials, which may be logistically complicated and hard to find financial support and infrastructure to implement. As an alternative, one could test an entire matching strategy against an alternative way of providing interventions (e.g., giving everyone the same intervention). This is more or less the motivation behind ‘basket’ and ‘umbrella’ trials currently in use, primarily in oncology settings.(35, 36) In oncology contexts, basket and umbrella trials enroll multiple individual patients into a trial knowing that they each might have unique features in their profile that could indicate that different interventions are appropriate. Basket trials enroll individuals without regard to the specific tissue affected by cancer (e.g., lung, breast and colorectal cancer patients can be enrolled) whereas umbrella trials only consider a single tissue (only lung cancer patients are enrolled). Each patient's tumor is profiled, usually via DNA sequencing. The tumor genome is analyzed to see if there are actionable ‘driver’ perturbations in the tumor, such as mutations affecting particular genes, that are likely contributing to the growth of the tumor. If the mechanisms of action of a group of interventions (i.e., cancer drugs) are understood well

Author Manuscript

Author Manuscript

Author Manuscript

Author Manuscript

enough, it may be possible to match those drugs to the perturbations in the tumor (e.g., if the EGFR gene is mutated and overexpressed in the tumor, then using a drug like cetuximab, which inhibits the EGFR gene, would be logical). Thus, each patient is steered towards a particular intervention basket (e.g., the EGFR inhibitor basket). The trial then seeks to test the hypothesis that the use of the different intervention baskets based on the matching scheme results in better outcomes than interventions provided to individual patients based on some other scheme that does not involve tumor profiling and matching.

If the trial is a failure (i.e., the matching scheme doesn't lead to better outcomes than something else), then an argument could be made that the matching scheme was flawed and not necessarily that the interventions considered in the trial are flawed. It would also be wrong to assume that the concept of personalized medicine is flawed as a result of a failure of a basket or bucket trial if in fact the matching scheme was found to be flawed. Some basket trials only have a single basket and no comparison group, but rely on determining which patient profiles appear to be associated with better outcomes for the intervention being tested.(37) Intervention matching schemes are likely to become the rule rather than the exception in medicine, especially since the introduction of computational environments like IBM's ‘Watson’ system. Essentially, Watson is system that includes a very large database extracted in part from the vast medical literature, providing links between information about a patient (e.g., genetic profiles, age, sex, etc.) to outcomes (such as drug response). These links have been enhanced by leveraging statistical methods to further assess relationships between patient profiles and outcomes. For example, Watson has been ‘trained’ to identify and establish links about perturbations often observed in a tumor and how those perturbations might be combatted by available drugs and interventions generally. Thus, if Watson was provided a patient profile, it could look up the best possible intervention given the current state of the science reflected in the literature and Watson's methods for establishing links between profiles and outcomes. The use of IBM's Watson system in actual clinical settings has led to discussions about how best to test and deploy such as a system as a way of supporting, as opposed to replacing, physicians' decisions about an intervention choice for individual patients.(38)

Adaptive Clinical Trials

Adaptive and sequential clinical trials have been used for decades but their consideration and use in personalized medicine contexts is much more recent.(35) Essentially, adaptive trials have as one of their focal points a desire to minimize the amount of time a patient is on what is likely to be an inferior therapy. In the context of personalized medicine, if there is equipoise with respect to available interventions or between an untested and a conventional intervention for an individual patient, then the evaluation of the effects of each intervention on an individual to determine the best one for that individual (as in a very elaborate N-of-1 study) might be impractical or cause more harm than good. This is the case because some, if not all, of the interventions might not actually benefit that individual. In this light, it makes sense to implement studies in which biomarkers reflecting response or adverse effects are collected on an individual trial participant and monitoring of those biomarkers is pursued to determine if there are signs an intervention is not working. If there are, e.g., signs that an intervention is not working, the individual could cross-over to a new intervention. Although

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

adaptive designs can be difficult to implement given their real-time evaluation and updating components, and can also produce data that might be more complicated to analyze than data from fixed, non-adaptive trials, they are often seen as more ethical. In addition, adding adaptive components to N-of-1 and aggregated N-of-1 trials as well as intervention-matching trials is possible. Although there are a growing number of papers describing adaptive trials, the work of Murphy and colleagues has received a great deal of attention because of its focus on minimizing the amount of time a patient is on an inferior treatment.(39-41)

Emerging and Next-Generation Personalized Medicine Strategies

There are a number of very recent research and clinical activities that are charting new territory for personalized medicine. We focus on four of these activities in the following, providing a brief overview of each. These activities include the use of patient-derived cell and organoid ‘avatars’ for determining the best therapies for that patient, the use of intense individualized diagnostic and monitoring protocols to detect signs of disease, the development of personalized digital therapeutics, and the use of personalized medicine approaches in treating patients with fertility issues.

Patient-Derived Cellular Avatars

It is now possible to harvest cells from individuals and use pluripotency induction (i.e., induced pluripotent stem cell or ‘iPSC’) methods on those cells to generate additional cell types of relevance to a patient's condition without having to directly biopsy the affected tissue. This allows researchers to essentially develop a ‘disease in a dish’ cellular model of a patient's condition.(42-44) These *in vitro* cellular ‘avatars’ can be studied to identify key molecular pathologies that might give an indication as to how best to treat an individual patient of interest. The use of iPSC technologies in this manner can be extended with a few additional, very recently developed, technologies to create even better models of an individual's condition. For example, if the patient has a known mutation causing his or her condition, it is possible to use assays based on, e.g., Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) and related constructs to create isogenic cells in which some cells have the mutation in question and some do not. Comparison of these cells allows direct insight into the effects of the mutation while controlling for all relevant genetic background effects associated with the patient's genome.(45, 46) In addition, it is possible to create partial organs or ‘organoids’ from cells obtained from an individual.(47) Organoids can provide greater insight into molecular pathologies associated with an individual patient's condition since they can model cell:cell interactions and more global tissue function.(48)

To achieve truly personalized medical care, the use of patient avatars derived from their own cells could be integrated with other pieces of information about a patient, as well as protocols for acting on that information. Schork and Nazor describe the motivation and integration of different aspects of patient diagnosis, intervention choice, and monitoring, using, among other things, patient avatars.(49) One important aspect of the use of cell-based patient avatars in personalized medicine is that they can accommodate personalized drug screening: literally testing thousands of drugs and compounds against a patient's cells (or

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

organoids, possibly modified with CRISPR technologies) to identify drugs or compounds that uniquely correct the patient's molecular defects. If the drug or compound has actually been approved for use, possibly for another condition, then it could be tested for efficacy with the patient in question under an approved drug ‘repurposing’ protocol. The use of patient-derived cells in personalized drug screening initiatives has shown some success in cancer settings, as tumor biopsies can yield appropriate material for drug screening.(48, 50) The biggest concern with this approach revolves around the question of whether or not the *in vitro* models capture relevant *in vivo* pathobiology and drug response information that may impact a patient's response to a chosen drug. A more direct strategy for *in vivo* experimental cancer intervention choice could involve implanting a device into a patient's tumor *in vivo* and then delivering different drugs through that device to see which ones have an effect.(51, 52)

Intensive Personalized Health Monitoring

The availability of inexpensive genotyping and sequencing technologies is allowing individuals and their health care providers to assess their genetically-mediated risk for disease and/or make a genetic diagnosis if they are already diseased. In addition, given the availability of health monitoring devices, online-ordered blood-based clinical assays, inexpensive imaging devices, etc. it is possible to continuously, or near continuously, monitor aspects of an individual's health (see Figure 1 and see the articles associated with the ‘quantified self’ movement: http://quantifiedself.com)(53, 54). With this in mind, combining genetic risk or diagnostic assessment with intense health monitoring makes sense. A number of individuals with unique diseases and conditions have benefitted from a genetic diagnosis, as it uncovered potential genetically-mediated pathogenic mechanisms or revealed potential targets for pharmacotherapies for them.(49) In addition, a number of individuals have monitored their health intensely for the express purpose of identifying signs of a health status changes, some of which might be attributable to genetic susceptibilities.(55) Table 1 lists examples of published studies exploring the utility of genetic assays in generating a diagnosis for individuals with idiopathic conditions (or what have been referred to as ‘diagnostic odysseys’) as well as published studies exploring the utility of near continuous monitoring to identify evidence for a health status change in an individual. Such diagnoses and monitoring are highly personalized by definition.(15, 16, 56)

Monitoring individuals for health status changes is not trivial, however, if the measures being collected have not been evaluated in a population. This is because there will be no established norms that can be contrasted to the measures collected on an individual to know if those measures are abnormal. However, the community is quickly recognizing the utility of establishing ‘personal thresholds’ for measures as opposed to ‘population thresholds,’ as discussed in the ‘Personalizing Early Detection Strategies’ section above (26, 27) As noted, population thresholds are established from epidemiologic and population survey data and include often-used thresholds for determining disease status such as a cholesterol level greater than 200 for heart disease or a systolic blood pressure greater than 140 mmHg for hypertension. Personal thresholds are established from longitudinal or legacy values of a measure collected on an individual and may be unique to the individual in question and their use in some settings suggests that they work better than population thresholds.(26)

Digital Therapeutics and Personalized App Content

The ubiquity of smart phones has attracted the interest of many researchers in the health professions as a vehicle for not only collecting health data through various ‘apps’ but also to provide advice, feedback, coaching, imagery, music, text-messages, or connections with other resources, that could benefit an individual with a particular condition or disease. This has led to the emergence of the concept of a ‘digital therapeutic:’ a smart phone app designed to treat and bring relief to an individual affected by a medical or psychological condition.(57) The content provided by a digital therapeutic app to an individual could vary depending on what is learned about that individual and his or her response to content provided in the app. In this way, the app can be personalized.(58) Many digital therapeutics have undergone evaluation for their ability to engage users and benefit them.(59) The US Food and Drug Administration (FDA) has created guidelines for registering digital therapeutics as bona-fide, insurance-reimbursable, approved health technologies, and has begun evaluating and approving many of them. The first approved digital therapeutic – an app for substance abuse – was approved by the FDA in 2017.(60) How easily digital therapeutics will be assimilated into the care stream is an open question.(61)

Personalized Interventions Involving Fertility and Sterility

Personalized medicine strategies and approaches can be applied to treatments for fertility, as many researchers have proposed. For example, it has been suggested that one could leverage ‘real world’ data of the type collected routinely on patients visiting reproductive medicine and fertility clinics (from, e.g., Electronic Medical Record (EMR) systems established at many hospitals and clinics), and use these data to in analyses exploring patterns, patient subgroups and individual patient profiles that could shed light on variation in fertility rates, responses to interventions to enhance fertility, etc. The results of these analyses could then guide future care for patients with fertility issues.(62) In the context of the use of digital medicine, proposals to develop smart phone apps that could provide personalized coaching content to enhance pregnancy have been put forth.(63). Genetic variants known to influence fertility have also been identified and could be used to support diagnoses or personalized intervention plans.(64)(65) Finally, adaptive trial designs have been proposed that could be used to assess the utility of personalized approaches to raising awareness about time to conception and fertility.(66)

In addition to these more traditional approaches to personalizing fertility interventions, there are a number of emerging strategies to enhance fertility in women that go beyond traditional ways of stimulating ovaries.(67) For example, it is now possible to cryopreserve a set oocytes and ovarian tissue samples from a woman and then implant them in her at a later time that may suit her desire to become pregnant.(68) Such a procedure would be highly personalized, since it would work with an individual's own cells and accommodate her preferences for becoming pregnant. However, this procedure would only work if the preserved tissues were viable and not damaged, although relevant cells in those tissues could, in theory, be corrected for genetic defects using gene editing techniques.(69) A more futuristic and controversial personalized fertility intervention, involves the concept that one could use cell reprogramming technologies to generate sperm and egg cells from other cells

obtained from an individual (e.g., skin cells) that could be edited to generate *de novo* gametes for fertilization – a concept known as '*in vitro* gametogenesis.'(70)

Conclusions

Personalized Medicine, or the practice of characterizing an individual patient on a number of levels (e.g., genomic, biochemical, behavioral, etc.) that might shed light on their response to an intervention, and then treating them accordingly, is a necessity given the fact that clinically meaningful inter-individual variation has, and will continue to be, identified. The availability of modern biomedical technologies such as DNA sequencing, proteomics, and wireless monitoring devices, has enabled the identification of this variation, essentially exposing the need for the personalization of medicine at some level. The future challenges associated with this reality will be to not only improve the efficiency in the way in which individuals are characterized, but also in the way in personalized medicines are crafted and vetted to show their utility. This is not to say that interventions that work ubiquitously (i.e., the traditional single agent 'block buster' drugs) should be ignored if identified, but rather that they might be very hard to identify going forward.

There are a few other issues associated with personalized medicine that may hard to overcome in the near term. For example, the need for large data collections in order to identify factors that discriminate groups of individuals that might benefit more from one or another intervention, could create concerns about privacy and the data about those individuals possibly being used for nefarious purposes.(71-73) Fortunately, this issue is not necessarily unique to health care settings, whether current or future, as it has plagued many other industries including the banking, marketing, and social media industries. Strategies exploited in these other industries could be used in health care settings as well. In addition, developing more efficient ways of developing personalized medicines (for example, with respect to cell replacement therapies or mutation-specific drugs that work for a small fraction of patients) is crucial to meet the demands of all patients. Also, paying for personalized medicine practices in the future may be complicated given that they might be initially more expensive.(74) Finally, in order for various stakeholders to embrace personalized medicine, better strategies to educate and train health care professionals about personalized medicine must be developed and implemented.

Imaging and Radiology
Environmental Exposures
Wireless Monitoring
Behaviors and Personality
Epigenetic Modifications
Individual Patient

Figure 1.

Graphical depiction of elements in need of integration and assessment in pursuing truly personalized medicine. Access to health care is important since some individuals may not be able to access expertise and technologies due to geographic or economic barriers and therefore interventions might need to be crafted for those individuals with this in mind. Inherited genetic information is really only predictive or diagnostic in nature however somatic changes to DNA can provide valuable insight into pathogenic processes. Tissue biomarkers (e.g., routine blood-based clinical chemistry panels) are useful for detecting changes in health status, as are imaging and radiology exams as well as data collected routinely via wireless monitors. Environmental exposures and behaviors can really impact the success of an intervention and exhibit great inter-individual variability. Epigenetic phenomena reshape gene function based on exposures and developmental or stochastic phenomena and should be monitored as well as indicators of a health status change.

A road map for understanding molecular and genetic determinants of osteoporosis

*Tie-Lin Yang[1], Hui Shen[2], Anqi Liu[2], Shan-Shan Dong[1], Lei Zhang[3], Fei-Yan Deng[3], Qi Zhao[4] and Hong-Wen Deng[2,5]**

Abstract | Osteoporosis is a highly prevalent disorder characterized by low bone mineral density and an increased risk of fracture, termed osteoporotic fracture. Notably, bone mineral density, osteoporosis and osteoporotic fracture are highly heritable; however, determining the genetic architecture, and especially the underlying genomic and molecular mechanisms, of osteoporosis in vivo in humans is still challenging. In addition to susceptibility loci identified in genome-wide association studies, advances in various omics technologies, including genomics, transcriptomics, epigenomics, proteomics and metabolomics, have all been applied to dissect the pathogenesis of osteoporosis. However, each technology individually cannot capture the entire view of the disease pathology and thus fails to comprehensively identify the underlying pathological molecular mechanisms, especially the regulatory and signalling mechanisms. A change to the status quo calls for integrative multi-omics and inter-omics analyses with approaches in 'systems genetics and genomics'. In this Review, we highlight findings from genome-wide association studies and studies using various omics technologies individually to identify mechanisms of osteoporosis. Furthermore, we summarize current studies of data integration to understand, diagnose and inform the treatment of osteoporosis. The integration of multiple technologies will provide a road map to illuminate the complex pathogenesis of osteoporosis, especially from molecular functional aspects, in vivo in humans.

**e-mail: hdeng2@tulane.edu*

https://doi.org/10.1038/s41574-019-0282-7

Osteoporosis, the most common bone disorder worldwide (FIG. 1), is characterized by low bone mineral density (BMD) and an increased risk of osteoporotic fracture[1]. According to the WHO, osteoporosis is defined as a BMD that lies 2.5 standard deviations or more below the average value for young healthy women (T-score $\leq$ 2.5)[2]. Consequently, the clinical diagnosis and assessment of osteoporosis is mainly based on measurements of BMD[3]. Of note, BMD has a heritability of 0.6–0.8, meaning that 60–80% of the variation in BMD is inherited from parents and the remainder is derived from the environment[4]. In addition, osteoporotic fracture, which is the end point clinical outcome of osteoporosis, has a heritability of 0.5–0.7 (REF.[5]). Despite this strong heritability, determining the genetic architecture (BOX 1), and especially the underlying genomic and molecular mechanisms of osteoporosis in vivo in humans, is challenging.

Genome-wide association studies (GWAS) have identified hundreds of susceptibility loci for osteoporosis[6]. However, the causal variants and/or genes and their molecular functional mechanisms are largely unknown. Other omics technologies, that is, transcriptomics, epigenomics, proteomics, metabolomics and metagenomics (BOX 1), individually might provide a useful glimpse into the windows of osteoporosis pathophysiology. However, data generated by single-omics technologies are not comprehensive enough to capture the complete pictures of the molecular events leading to osteoporosis. A change in the status quo calls for integrative multi-omics and/or inter-omics analyses with approaches in systems genetics and genomics.

Compared with individual-omics studies, multi-omics studies can provide pathways of information from the original root cause of a disease (for example, genetic variations) to functional consequences or relevant interactions[7,8]. Therefore, multi-omics data can provide a clearer and more comprehensive view of the pathogenesis of osteoporosis. This knowledge is important as it is not currently possible to accurately identify all patients who will experience osteoporotic fracture from measurements of BMD.

Key points

- Osteoporosis, which is the most common bone disorder worldwide, and its related traits (low bone mineral density and osteoporotic fracture) are highly heritable.
- Multiple omics technologies, including genomics, transcriptomics, epigenomics, proteomics and metabolomics, have been applied to identify the molecular factors contributing to the pathogenesis of osteoporosis.
- Building upon the success in single-omics discovery research, studies have integrated data from different omics levels to better elucidate the molecular and functional mechanisms for osteoporosis.
- Integration of omics approaches can provide a holistic road map to comprehensively illuminate the complex pathogenesis of osteoporosis and fulfil the potential of personalized disease risk prediction, intervention and treatment as well as drug development or re-purposing.

In this Review, we briefly introduce the mechanisms of bone homeostasis before providing a broad survey of GWAS and the multiple-omics studies on osteoporosis (FIG. 2). We discuss the advantages and challenges of each technology and then focus on studies in which multiple levels of omics are integrated to elucidate the potential molecular mechanisms for osteoporosis. We also discuss the current methods and challenges in combining and interpreting multi-omics data in osteoporosis studies.

Bone homeostasis

Bone homeostasis is mainly controlled by the action of osteoblasts, osteocytes and osteoclasts; bone is a highly metabolically active tissue, which undergoes a continuous cycle of bone formation mediated by osteoblasts and bone resorption facilitated by osteoclasts. Importantly, disruption of bone homeostasis has a fundamental role in the pathogenesis of osteoporosis[9].

The cells that comprise bone tissue have diverse origins. For example, osteoblasts are derived from mesenchymal stem cells, which can also give rise to adipocytes, chondrocytes and myocytes[10] (FIG. 3). Osteoblasts produce bone by synthesizing extracellular matrix consisting of various proteins, the most abundant being type I collagen. The extracellular matrix is known as the osteoid when first deposited and is subsequently mineralized through the accumulation of calcium phosphate as hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$). Multiple transcription factors (such as RUNX2 and OSX) and the major developmental signals (such as WNT signalling) are reported to regulate osteoblast differentiation and function[11]. By contrast, the bone resorbing osteoclasts are large, multinucleated cells formed by the fusion of precursors from the monocyte-derived macrophage lineage[12] (FIG. 3). Osteoclasts can dissolve minerals and digest bone matrix by secreting hydrochloric acid and proteolytic enzymes[13]. Similar to osteoblasts, multiple factors are reported to regulate osteoclast differentiation and/or function, including macrophage colony-stimulating factor (M-CSF), receptor activator of nuclear factor-κB ligand (RANKL), cytokines (for example, IL-1) and αVβ3 integrin[14].

The major cellular component of bone tissue is osteocytes, which are cells that originate from osteoblasts; these cells are deeply embedded in bone tissue and comprise >90% of all bone cells[15]. Osteocytes can orchestrate bone homeostasis by regulating the function of bone-forming osteoblasts and bone-resorbing osteoclasts. For example, osteocytes regulate bone formation by secreting modulators of the WNT signalling pathway such as activators (nitric oxide and ATP) and inhibitors (sclerostin and DKK1)[16]. Moreover, osteocytes also express RANKL and M-CSF to increase osteoclast activity as well as osteoprotegerin and nitric oxide to inhibit osteoclast formation and activity[16]. A detailed description of the crosstalk between the three major bone cellular subsets falls outside the scope of this Review, but can be found in REF.[17].

The genome influences the maintenance of bone homeostasis by encoding many factors that modulate the differentiation and activities of bone cells. In addition to several components in the aforementioned signalling pathways, hundreds of common genetic variants associated with BMD or osteoporotic fracture have been discovered. Beginning in the next section, we will present an update on what is known about genetic risk factors for osteoporosis.

Susceptibility loci derived from GWAS

Mainly through testing millions of single nucleotide polymorphisms (SNPs), GWAS have been used to identify over 500 susceptibility loci for osteoporosis-related traits[18–20] (Supplementary Table 1). The sample sizes of early single-sample GWAS were fairly small (<10,000)[21–24], resulting in limited statistical power; indeed, only risk loci with an effect size (BOX 1) ranging from 7.8×10^{-4} to 1.4×10^{-2} could be identified[21–24] (BOX 2). However, with the increases in sample size and improvements in statistical power, GWAS meta-analyses can identify more risk loci with effect sizes of 10^{-4} to 10^{-3} (BOX 2). For example, the GEnetic Factors for OSteoporosis (GEFOS) consortium, which consists of unrelated participants and sample sizes ranging from 19,195 to 66,628, has identified dozens of new susceptibility loci (such as *EN1*)[25] and has replicated some risk loci identified by earlier GWAS[26–30] (such as *ESR1* and *LRP5*). In mice, *En1* expression was only observed in osteogenic lineages, and conditional loss of *En1* resulted in low bone mass[25]. As the oestrogen receptor, ESR1 affects bone formation in both osteoblasts progenitors[31] and mature osteoblasts[32]. ESR1 could also induce the transcription of Fas ligand in osteoblasts, resulting in a paracrine signal to induce osteoclast apoptosis[31]. In the canonical WNT signalling pathway in bone formation, the activation of β-catenin through LRP5 and Frizzled results in the upregulation of transcription factors that are crucial for osteoblast differentiation[33] (FIG. 3). Together, the loci identified from GEFOS cumulatively explained ~6% of the phenotypic variance in BMD.

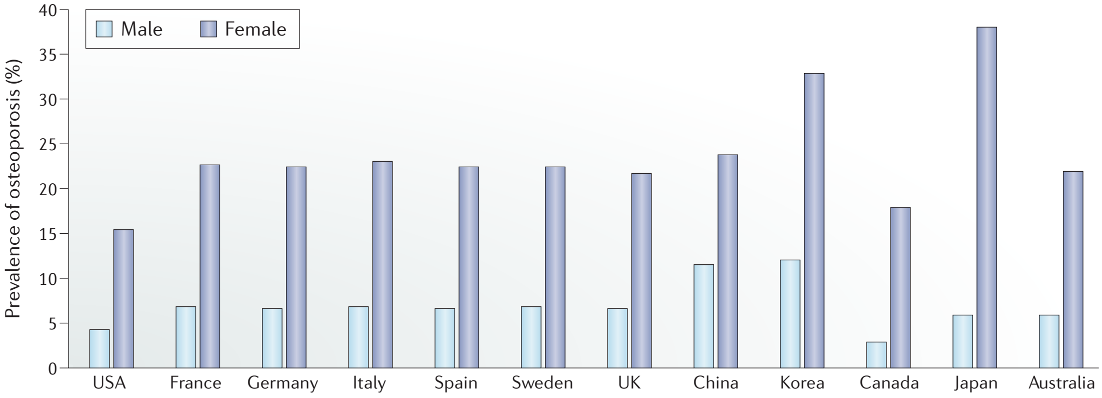

Fig. 1 | **Prevalence of osteoporosis in populations of age 50 years and older in selected countries.** The prevalence of osteoporosis in the non-institutionalized USA population was calculated using data collected by the National Health and Nutrition Examination Survey 2005–2010 (REF.[153]). The statistics for six European countries (France, Germany, Italy, Spain, Sweden and the UK) were retrieved from a report by the International Osteoporosis Foundation[154]. The statistics for China and Korea were obtained from a meta-analysis study published in 2016 (REF.[155]) and the Korea National Health and Nutrition Examination Survey 2008–2010 (REF.[156]), respectively. Data for Canada, Japan and Australia were obtained from a 2014 study[157].

The UK Biobank project[34] is remarkable due to its huge number of samples obtained from participants from the UK general population. Importantly, two GWAS in ~140,000 and 420,000 UK Biobank participants have identified 203 and 518 loci, respectively, associated with variation in ultrasound-based measurements of estimated heel BMD (eBMD)[6,35] (FIG. 3). For example, DAAM2 was identified in a UK Biobank study; reduction of DAAM2 protein levels resulted in reduced bone mineralization[6]. In addition, the largest UK Biobank cohort has nearly 100% power to identify loci with an effect size of 1×10^{-5} (BOX 2). The loci identified from studying the UK Biobank cohort can cumulatively explain 20% of the phenotypic variance in eBMD, therefore substantially increasing our understanding of the genetic architecture of osteoporosis.

Several groups have also used GWAS to carry out age-specific and sex-specific analyses[30,35]. Variants in *ESR1* and in close proximity to *RANKL* showed a clear age-dependent effect on BMD[30]. A single variant, rs17307280, at *FAM9B* on the X chromosome was significantly associated with eBMD in men only[35]. The function of FAM9B in bone homeostasis is still unknown. Of note, a direct link exists between oestrogen deficiency after menopause and the development of osteoporosis[36] in women. Consequently, researchers have also attempted to investigate specific risk loci in premenopausal[37] and postmenopausal[38] women. SNPs in *WNT16* and *ESR1* were identified to be associated with lumbar spine BMD in premenopausal women[37]. *WNT16* is a member of the WNT signalling pathway and *Wnt16* knockout mice have reduced bone strength[39]. In postmenopausal women[38], variants in *TNFRSF11B*, *SPTBN1*, *ESR1* and *LRP4* were reported to be susceptibility loci for osteoporotic fracture. The protein encoded by *TNFRSF11B* is osteoprotegerin, which functions as a decoy receptor of RANKL to inhibit bone resorption[40]. In vivo evidence suggested that LRP4 in osteoblasts could suppress bone formation and promote osteoclastogenesis through acting as a receptor of sclerostin[41].

The missing heritability problem. The BMD-associated loci identified so far in GWAS still cannot account for all the heritability in osteoporosis. Consideration of gene–environment interactions might explain part of this ‘missing heritability’[42]. Researchers could explore gene–environment interactions through investigating the effects of genetic variants on osteoporosis in specific population subgroups affected by specific environmental factors (for example, smoking). In addition, many alternative approaches have been developed to serve as complementary methods for the standard SNP-based GWAS described earlier in this Review. For example, copy number variation-based GWAS focus on identifying variation in gene copy number. The first copy number variation-based GWAS identified that a deletion variant of *UGT2B17* was associated with hip osteoporotic fracture[43]. *UGT2B17* encodes an enzyme catabolizing steroid hormones that have effects on bone formation[43].

Another useful approach is that used in gene-based GWAS, which regard a gene as a basic unit for association analyses, thereby improving the statistical power (BOX 2) by overcoming the potential allelic heterogeneity (BOX 1) and reducing the number of independent statistical tests from millions (for SNPs) to tens of thousands (for genes)[44]. A 2018 study found three novel BMD-associated genes (*UBTF*, *AAAS* and *C11orf58*) through a gene-based GWAS strategy[44]. The roles of the proteins encoded by these three genes in bone homeostasis are still unknown. A powerful technique for identifying biological pathways that might be involved in a heritable trait is pathway-based GWAS, which considers SNPs in multiple genes in a related pathway jointly. The first pathway-based GWAS for osteoporosis identified a pathway that regulates autophagy as being associated with ultradistal radius BMD[45]. In addition to overcoming the effect of allelic heterogeneity and improving statistical power, gene-based GWAS and/or pathway-based GWAS also enable direct comparison between different populations with different linkage disequilibrium patterns and/or functional alleles[46].

Box 1 | **Key terms in genetic and omics studies**

Allelic heterogeneity
Multiple single nucleotide polymorphisms within the same gene and/or pathway jointly affect the same trait.

Distant gene
If a genetic variant affects the expression or otherwise interacts with genes other than the nearest gene, the target genes are referred as distant genes of the variant of interest.

Effect size
The portion of phenotypic variance that is explained by the tested variant.

Epigenomics
The study of genome-wide reversible modifications of DNA or DNA-associated proteins such as DNA methylation, histone acetylation and chromatin organization.

Expression quantitative trait loci (eQTL) analysis
A technique for assessing the associations between transcript expression and genotype to identify genetic variants that explain the variation in gene expression levels.

Fingerprint
Specific expression profiles of proteins, which can be used as characteristics to distinguish different individuals.

Genetic architecture
The characteristics of genetic variation that are responsible for heritable phenotypic variability[150].

Genome-wide association studies (GWAS)
Studies using a hypothesis-free method to investigate the associations between genetic variants and traits, including diseases.

Hybrid mouse diversity panel
A collection of approximately 100 well-characterized inbred strains of mice that can be used to analyse the genetic and environmental factors underlying complex traits.

Knowledgebase
A library used to store complex structured and unstructured information by a computer system.

Long-range
The distance between regulatory regions and their target genes is considered far, usually >100 kb.

Mendelian randomization
Mendelian randomization is a method of using genetic variants to determine whether an observational association between a risk factor and an outcome is consistent with a causal effect.

Metabolomics
A field of omics science to systematically measure small molecules, commonly knowns as metabolites, within cells, biofluids, tissues or organisms.

Ome
The objects of one field of study in biology, for example, the genome, proteome or metabolome.

Proteomics
The identification and quantification of the entire protein complement of a cell, tissue or organism under a specific, defined set of conditions.

Transcriptomics
The study of the complete set of RNA transcripts (including messenger, transfer, ribosomal and non-coding regulatory RNAs) produced by a cell or tissue under specific conditions.

Weighted gene co-expression network analysis (WGCNA)
A commonly used systems biology method for studying the correlation patterns among genes. WGCNA can be used for finding clusters (referred to as modules) of genes sharing similar expression patterns across a set of samples, and for relating modules to disease status and sample traits using module behaviour and topology characteristics.

Bivariate GWAS aim to discover SNPs associated with two different traits and could identify pleiotropic genes as well as the key mechanistic links between two diseases. Any identified pleiotropic genes could provide insight into a genetic mechanism shared by both traits as well as potentially facilitating repurposing of conventional drugs used for one disease for new use in the other. A relevant example in osteoporosis research was a study identifying SNPs in *SOX6* (REF.[47]) and the *TOM1L2–SREBF1* locus[48], which have pleiotropic effects on both BMD and lean mass. Finally, summary databased approaches, such as joint association studies[49], pleiotropic conditional false discovery rate method[50] and co-expression network prediction[51], which are methods that use GWAS summary statistics alone, have also identified a large amount of novel BMD loci.

Clinical translation of GWAS findings. To address the missing heritability problem, researchers could explore more loci under an omnigenic model[52], which proposes that gene regulatory networks are so interconnected that most heritability can be explained by effects on genes outside core pathways. New findings will provide novel insights into the genetic mechanism of osteoporosis as well as osteoporosis risk prediction. For example, two studies[53,54] have reported that genetic profiling of BMD-associated SNPs could improve the accuracy of osteoporotic fracture prediction. In addition, a genetic algorithm that uses SNPs as predictors also showed a strong correlation with eBMD (correlation coefficient $R = 0.415$)[55]. By contrast, for clinical applications such as drug target design, loci with large genetic effects on BMD and osteoporotic fracture risk might be more valuable. We should spare no effort to dissect the clinical applications of known risk loci, which is an ultimate goal of all GWAS.

The success of GWAS demonstrates the usefulness of disease genomics to translational medicine. Generally, compared with those without genetic support, drug targets that are reported as susceptibility loci in GWAS are twice as likely to succeed in clinical trials[56]. For osteoporosis, GWAS have provided genetic support for five of the eight (63%) approved anti-osteoporosis therapeutics. For example, *RANKL* is the drug target of denosumab and the genetic association between *RANKL* and BMD has been reported by GWAS[18]. In addition, GWAS results could provide resources for drug repositioning. Some of the susceptibility loci for BMD and osteoporotic fracture are shared with many other diseases and, consequently, some osteoporosis-associated genes have already been used as drug targets for other diseases (Supplementary Table 2). For example, the eBMD-associated gene *ACHE* is an approved drug (donepezil) target for Alzheimer disease. Accumulating evidence[57,58] has indicated that osteoporosis and hip fracture are common complications observed in patients with Alzheimer disease, although the mechanisms underlying this association remain poorly understood. In addition, as an inhibitor of ACHE, donepezil might serve as a potential drug for osteoporosis as it could prevent RANK-induced bone loss via inhibition of osteoclast differentiation[59].

The challenges of GWAS. Several challenges exist for the use of GWAS in osteoporosis, which should be addressed in future studies. For example, diverse phenotypes (BMD at different skeletal sites using different measurements) are now included in osteoporosis GWAS, resulting in inconsistent results. The inconsistencies might be due to the heterogeneity among the different types of measurements of BMD, as the genetic correlation coefficients between the commonly used dual-energy X-ray absorptiometry and other measurements (for example, ultrasonography and quantitative CT) range from 0.505 to 0.917 (REF.[60]). However, even when studies use the same type of measurement, there is still heterogeneity between BMD measured at different skeletal sites. In addition, as the ultimate goal of osteoporosis research is to reduce the incidence and prevalence of osteoporotic fracture, GWAS should use osteoporotic fracture as a direct phenotype. Several novel genes (such as *FAM210A*, *GRB10* and *ETS2*) have been identified as susceptibility loci by GWAS directly comparing individuals who have had an osteoporotic fracture and healthy controls[61]. The specific functions of these genes in bone homeostasis are still unknown. However, most of these studies combined heterogeneous forms of osteoporotic fracture at different skeletal sites, which have different aetiologies; the results obtained might therefore entail both false positive or false negative findings, which are difficult to discern. Two studies examined osteoporotic fracture at specific sites: vertebral fracture[62] and hip fracture[63]. Two SNPs (rs2468531 and rs12742784) located in the non-coding region were found to be associated with vertebral fracture[62]. One SNP (rs13182402) within the *ALDH7A1* gene was associated with hip fracture. The ALDH7A1 protein degrades and detoxifies acetaldehyde, which inhibits osteoblast proliferation and results in decreased bone formation[63]. We suggest that vertebral fracture might not be the best phenotype to study, as no consensus definition of vertebral fracture currently exists. By contrast, hip fracture has a consensus definition and might represent a feasible alternative for study.

The replication of findings in distinct GWAS is a routine process for validating the statistical results from the discovery sample[64,65]. However, inconsistent findings that occur between different studies might be caused by limited statistical power (BOX 2) or heterogeneous effects[66] between distinct populations and ethnicities[64]. These effects could explain discrepancies between studies, and even the different findings between GEFOS-1 and GEFOS-2 (REFS[26,28]), which were conducted by largely the same research group. Future meta-analyses of GWAS should enable researchers to fully consider the heterogeneity.

Another potential issue of GWAS is the difficulty in determining the causal variants of a specific phenotype owing to complex patterns of linkage disequilibrium. Some statistical inference methods, such as PAINTOR[67], GCTA-COJO[68] and FINEMAP[69], have been applied for the fine-mapping of plausibly causal variants for BMD with high confidence[6,35,70]. However, most fine-mapping algorithms need reference genotype data to estimate the linkage disequilibrium relationship between genetic variants, which introduces inescapable bias when the reference data and original GWAS data are not perfectly matched[71].

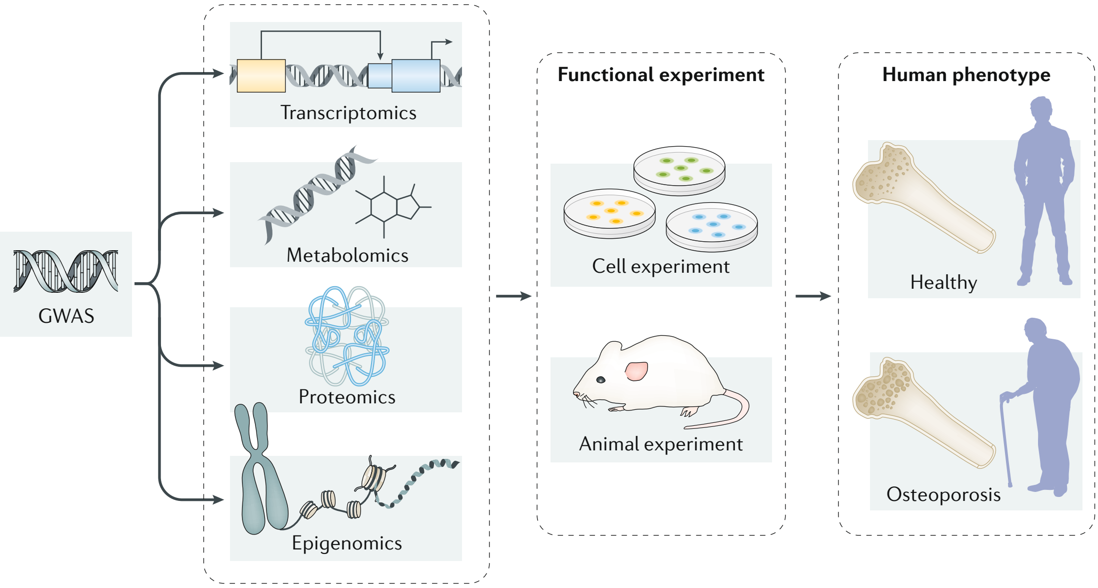

Fig. 2 | **Integrating multi-omics data to elucidate the molecular mechanisms of osteoporosis.** Multiple omics technologies, including genomics (mainly refers to genome-wide association studies (GWAS)), transcriptomics, epigenomics, proteomics and metabolomics, have been applied to dissect the pathogenesis of osteoporosis. Each technology individually can only provide limited insights into the biological mechanisms of osteoporosis. By integrating multiple omics data and following-up functional experiments in cell lines and/or animal models, researchers could capture a comprehensive view of the pathogenesis of this disorder.

Finally, although GWAS have identified hundreds of independent loci for osteoporosis-related traits (Supplementary Table 1), the underlying causal functional variants and biological regulatory mechanisms are still largely unknown. The use of GWAS alone might not be able to address these issues; however, considering functional genomics could provide new insights.

Insights from 'omics' studies

Functional genomics and other omics studies, which focus on, for example, global gene transcription, translation and protein–protein interactions, have identified a list of biomarkers for osteoporosis, providing insights into the biological pathways involved. Here, we review these studies, including transcriptomics, epigenomics, proteomics and metabolomics (BOX 1).

Transcriptomics. Transcriptomics studies are used to identify differentially expressed genes between patients with osteoporosis and control individuals. Further functional experiments are used to validate the roles of these genes in osteoblastic and osteoclastic differentiation and/or activity. So far, most of the research has studied the precursor cells of osteoblasts (that is,

Fig. 3 | **Differentiation process of osteoblasts and osteoclasts.** Bone is a highly metabolically active tissue, which undergoes a continuous cycle of bone formation mediated by osteoblasts and bone resorption facilitated by osteoclasts. The cells that comprise bone tissue have diverse origins. Osteoblasts are derived from mesenchymal stem cells, which can also give rise to adipocytes, chondrocytes and myocytes. Osteoclasts are large, multinucleated cells formed by fusion of precursors derived from the monocyte–macrophage lineage. As the major cellular component of bone tissue, osteocytes originate from osteoblasts. We list several representative genes linked to bone metabolism by omics studies; functional experiments support their involvement in bone homeostasis. GWAS, genome-wide association studies; PTHR, parathyroid hormone receptor.

Box 2 | Statistical power calculations

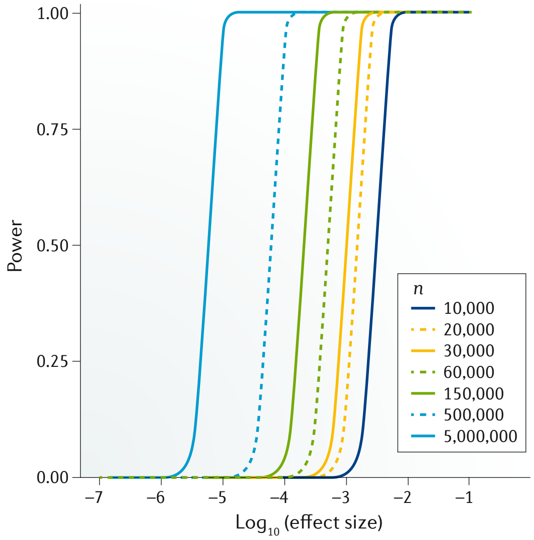
Statistical power is important in genome-wide association studies (GWAS) as it is the parameter that determines how effectively a given study will identify susceptibility loci. The statistical power of statistical significance is the probability that an association test statistic will reject a false null hypothesis. As an association test statistic asymptotically (that is, approaching a curve arbitrarily closely) follows a 1-degree of freedom, non-central χ^2 distribution, statistical power is solely determined by the non-centrality parameter λ of this distribution ($\lambda \geq 0$).

Statistical power is confounded by a variety of factors, including cryptic relatedness (individuals are more closely related to one another than assumed by the investigator) and population stratification[151]. In an ideal scenario in which an unrelated sample (that is, of individuals that are independent from each other) is drawn from a homogeneous population and under an additive mode of inheritance, the non-centrality parameter λ has a simple form[152]:

$$\lambda \approx \mathrm{N} \times \mathrm{e}$$

where N is the sample size and e is the effect size, which is defined as the portion of phenotypic variance that is explained by the target variant, that is, variant-level heritability.

Of note, statistical power is non-relevant to variant allele frequency. Therefore, to detect associated variants of $\frac{1}{n}$ of the original effect size, the sample size should increase to n times the original sample size to reach the same level of statistical power. Refer to the figure to see the power calculated under several typical sample size settings for a GWAS scan (type I error rate threshold $\alpha = 5 \times 10^{-8}$). For any given sample size, the range of effect size with intermediate power falls into a relatively narrow interval. For example, under the largest sample size shown in the figure (5,000,000), this GWAS setting has nearly 100% power to detect variants with effect size $> 1 \times 10^{-5}$ but nearly 0% power to detect variants with effect size $< 1 \times 10^{-6}$.



human bone marrow mesenchymal stem cells (BMSCs)) or osteoclasts (for example, circulating monocytes) (Supplementary Table 3).

The first comparative gene expression study of circulating monocytes was carried out in individuals with high or low lumbar spine BMD measured with dual-energy X-ray absorptiometry and identified three upregulated genes (*CCR3*, *HDC* and *GCR*) in participants with low BMD[72]. The products of these genes are CC-chemokine receptor 3 (CCR3), histidine decarboxylase and glucocorticoid receptor, respectively. They are all known to be involved in osteoclastogenesis[73–75]. In addition to mRNA, the levels of non-coding RNA, such as microRNA[76], long non-coding RNA (lncRNA)[77] and circular RNA[78], have also been studied. For example, a 2019 study[77] reported that lncRNA-ORLNC1 was overexpressed in bone tissues of patients with osteoporosis compared with controls, with a T-score ≥1, and were also upregulated in bone tissue, serum and BMSCs of ovariectomy-induced osteoporotic mice compared with the sham-operated group. Further functional studies in BMSCs of mice showed that a lncRNA-ORLNC1–miR-296–PTEN signalling axis functions as a critical regulator for the switch between the osteogenesis and adipogenesis of BMSCs, that is, whether or not these cells differentiate into osteoblasts or adipocytes (FIG. 3).

Except for a few studies focused on a particular gene, for example, a synonymous variant in exon 9 of *CD44* that might increase the susceptibility to osteoporosis by affecting the splicing mechanism[79], transcriptomics studies of osteoporosis generally do not consider alternative splicing. Of note, alternative splicing is a ubiquitous regulatory mechanism of gene expression and RNA mis-splicing is related to a large array of human diseases[80]. Therefore, transcriptomics studies that take alternative splicing into consideration are needed in the field of bone research.

Epigenomics. Epigenetic factors, mainly DNA methylation and histone modification, have considerable effects on the differentiation and activities of bone cells[81] and might contribute to pathogenetic mechanisms of osteoporosis[82]. The early epigenetic studies of osteoporosis often focused on a few candidate genes with known importance in bone biology (Supplementary Table 4). For example, one study compared the DNA methylation levels at the *SOST* promoter region in bone biopsy samples from postmenopausal women with osteoporosis ($n = 4$) and healthy controls ($n = 4$)[83]. They found that the *SOST* promoter showed higher DNA methylation in patients with osteoporosis than in controls, which was replicated in an independent cohort of 63 postmenopausal women (27 with osteoporosis and 36 without osteoporosis). Interestingly, the authors also observed strong positive associations between bone *SOST* mRNA and serum levels of sclerostin with BMD. Because sclerostin is known as an inhibitor of bone formation[84], the authors speculated that the increase in *SOST* promoter methylation and the reduction of *SOST* expression in patients with osteoporosis might represent a compensatory mechanism to counteracting osteoporosis-associated bone loss. However, conflicting results were reported by a 2019 study comparing femoral bone tissues from 16 Chinese patients with osteoporosis who had femoral neck and/or trochanter fractures and 16 controls (patients with traumatic factures but normal BMD), wherein *SOST* gene expression (at both mRNA and protein levels) was significantly increased and *SOST* promoter was slightly hypomethylated in patients with osteoporosis[85]. Therefore, the association between *SOST* methylation and expression with osteoporosis warrants further investigation.

Importantly, a few groups have explored the epigenome-wide association study (EWAS) of DNA methylation with osteoporosis in humans (Supplementary Table 4). For example, in 2013, the first EWAS of human bone detected 241 differentially methylated CpG sites in femoral head trabecular bone specimens between 27 patients with osteoporotic hip fractures and 26 patients with hip osteoarthritis[86]. Bone samples from true control individuals were not available owing to the ethical difficulties in obtaining bone biopsy samples from healthy people. So far, the largest EWAS using bone specimens were performed in 84 postmenopausal women with substantially varied BMD[87] and identified 63 differentially methylated CpGs associated with BMD.

Owing to the difficulty in obtaining human bone tissue samples, some EWAS (Supplementary Table 4) used whole blood as a proxy to test for the associations of DNA methylation with osteoporosis and BMD. One notable example study performed a large-scale EWAS for femoral neck and lumbar spine BMD in whole blood of 5,515 individuals[88]; however, the study did not reveal strong consistent association signals for DNA methylation at any of the >450,000 tested CpG sites. The lack of statistically significant associations between blood DNA methylation and osteoporosis was also reported in another independent EWAS[89]. Together, these findings suggest that blood DNA methylation patterns might not efficiently reflect the epigenomic status of bone cells if whole blood is used.

It is worth mentioning that aside from DNA methylation, other epigenetic features (for example, histone modification and high-order chromatin structure) have rarely been studied for osteoporosis[82]. Compared with many other human tissues and cell types, current data on the epigenetic architecture of human primary bone tissue and cells are rather scarce, even in large-scale consortium projects such as ENCODE[90] and NIH Roadmap[91].

Proteomics. To further investigate the molecular determinants of BMD, proteomics studies have been carried out to catalogue proteins expressed in bone-related cells or tissues, to identify proteins that are involved in the pathogenesis of osteoporosis, and to investigate protein biomarkers that are diagnostic of osteoporosis or predictive of osteoporotic fracture. Importantly, a 2008 study identified 38 differentially expressed BMD-associated proteins from the proteome of circulating monocytes in Chinese premenopausal women with discordant hip BMD[92]. The significance of ANXA2 and GSN proteins to osteoporosis was later cross-validated in independent cellular proteomics studies in white women with varying BMD[93,94]. Of note, ANXA2 could regulate osteoclastogenesis[93] (FIG. 3) and the function of osteoblasts[95], and increased plasma levels of this protein were shown to serve as a risk biomarker for osteoporosis and to predict osteoporotic fracture in Chinese individuals aged over 65 years[95]. The first comprehensive proteome knowledgebase (BOX 1) for human monocytes, developed in 2017 (REF.[96]), involves a total of 2,237 unique protein-encoding genes and provides a reference map for future in-depth research on monocyte biology and osteoporosis.

In addition to protein biomarkers developed from cellular proteomics studies, a number of potential protein biomarkers have been identified directly from plasma or serum proteomics studies. For example, one group identified a diagnostic fingerprint (BOX 1) for bone turnover in the serum of postmenopausal women, which could serve as a reflection of the increased osteoclast activity, leading to increased bone turnover, that is associated with decreasing BMD[97]. Besides, multiple layers of evidence were integrated to further ascertain the significance of proteins and genes of interest for osteoporosis. For example, a prior proteomics study discovered that superoxide dismutase 2 (SOD2) in circulating monocytes was significantly upregulated at protein level in vivo in Chinese individuals with low versus high hip BMD[92]. By integrating evidence from DNA, RNA and protein levels, a pursuant study ascertained *SOD2* as a susceptibility gene for osteoporosis in Chinese populations[98]. Furthermore, proteome-based network and pathway studies identified important groups of proteins for osteoporosis[99,100]. For example, a mass spectrometry-based quantitative proteomics study integrated with network analysis identified two novel pathways, that is, regulation of actin cytoskeleton and "leukocyte transendothelial migration" as being related to osteoporosis[96].

Some serum or plasma-derived protein biomarkers with diagnostic potential for osteoporotic fracture were identified from cross-sectional studies (Supplementary Table 5). Furthermore, serum-derived protein biomarkers predictive of incident osteoporotic fracture were identified from prospective studies (Supplementary Table 6). For example, a prospective study[101] suggested that increased serum levels of sclerostin are associated with increased risk of hip fracture. Excitingly, the antibody of sclerostin, that is, romosozumab (Evenity), has been approved by the FDA as a novel drug to treat osteoporosis in postmenopausal women with high risk of fracture.

Metabolomics. The human metabolome (BOX 1) reflects downstream changes in gene sequence and gene and/or protein expression. Thus, small changes in genes, their transcription and the translation of proteins that are hard to detect in other omics studies can be amplified at the metabolomic level[102], enabling the most powerful screening of biomarkers or therapeutic targets closely related to disease or phenotype. Of note, preclinical studies carried out in postmenopausal osteoporosis animal models have shown different metabolomic profiles compared with control animals, especially regarding changes in amino acid and lipid metabolism[103,104].

The first metabolomics study of osteoporosis in humans compared high and low BMD groups and reported four distinguishing metabolites: lactate, acetone, acetate and glutamine[105]. Subsequently, eight metabolomics studies investigating osteoporosis in humans have been published and have reported >100 metabolites associated with BMD (Supplementary Table 7). In line with the findings of animal studies, human studies also highlight the importance of amino acid and lipid metabolism in bone. In particular, many amino acids were reported to be associated with BMD by multiple independent studies[105–109]. For example, glutamine is increased[107,110] and proline is decreased in menopausal women with decreased BMD[109]. Moreover, carbohydrate[108] and nucleoside[106] metabolism are also altered in women with decreased BMD. Finally, BMD-related metabolic pathways have been reported, including bile acid biosynthesis, which might affect intestinal calcium absorption[107], and the tricarboxylic acid cycle, which might be related to increased oxidative stress in patients with low BMD[108].

Metabolomics research of osteoporosis is in the early stages. For example, all the current studies (Supplementary Table 7) are cross-sectional. Although two studies used Mendelian randomization (BOX 1) to provide potential evidence for a causal relationship of identified metabolites with osteoporosis[110,111], well designed longitudinal studies are necessary. In addition, potential sex differences in osteoporosis-related metabolites should be investigated, as most published studies only include women. For meaningful data generation, metabolite identity validation and absolute quantification should follow untargeted metabolomics analysis, which was used in all the current studies. These steps are necessary for conducting functional research of identified metabolites to derive meaningful biological knowledge[112].

Summary. Currently, functional genomics and other omics studies of osteoporosis have limitations, for example, the use of inappropriate tissue and/or cell specimens, small sample sizes and subsequent low statistical power, poorly characterized cohorts, and/or lack of healthy control individuals. Normal bone samples from healthy individuals are difficult to obtain as bone biopsy is invasive and carries a small risk of bleeding, fracture and/or infection. Consequently, bone samples obtained by biopsy from patients with osteoarthritis have been used as surrogate controls in several studies of osteoporosis[86]. However, the use of osteoarthritis bone samples might not be an ideal study design, as it is questionable to what extent cells from osteoarthritis bone resemble normal bone cells. Several studies have suggested that the trabecular structure and gene expression of osteoarthritis bone, at least in the vicinity of articular tissue, might differ from those of normal healthy bone[113,114].

In contrast to genetic variants, functional genomic and other omics changes are cell and tissue specific and therefore studies must be performed in bone or bone lineage cells. Moreover, bone itself is a heterogeneous tissue, composed of a number of different cell types (FIG. 3) and failure to account for the cellular heterogeneity might lead to false-positive or false-negative results[115,116]. A large consortium aiming to generate large-scale data for bone or bone lineage cells, such as the Cancer Genome Atlas Program for cancer, would greatly improve our ability to understand, diagnose, treat and prevent osteoporosis.

An integrative approach

Although each omics approach has provided useful information to begin to understand the pathophysiology of osteoporosis, no single omics approach (BOX 1) can capture the entire biological complexity of osteoporosis. Thus, approaches to integrate multi-omics data have emerged to create a holistic picture of osteoporosis. Next, we describe ways in which integrative multi-omics can help GWAS loci interpretation and the identification and prioritization of osteoporosis-related genes and pathways.

Integrating multi-omics data to interpret GWAS. The function of genetic variants located in coding regions of DNA, that is, in exons, is straightforward to study. However, the majority of GWAS susceptibility loci are located in non-coding or intergenic regions[117], which poses challenges to the functional interpretation of risk variants and the translation of GWAS findings into clinical application. Therefore, the first crucial step is to prioritize and/or pinpoint the true causal and/or functional variants[118].

A complementary approach to fine-mapping is to leverage multiple layers of epigenomic or functional data to assign potential functions for genetic variants identified by GWAS. For example, the assay for transposase-accessible chromatin using sequencing (known as ATAC-seq) is widely used to evaluate the accessibility of chromatin at the location of possible functional GWAS variants. Databases like RegulomeDB[119] can also be used to annotate SNPs with known and predicted regulatory elements such as regions of DNase I hypersensitivity and binding sites of transcription factors. The systematic analyses of the epigenetic features in all known osteoporosis risk loci identified by GWAS could identify common regulatory elements for osteoporosis-associated genes and might predict new osteoporosis-linked genes with similar regulatory features[120]. Using machine learning algorithms, researchers can extract intricate regulatory information underlying GWAS variants and use this knowledge to predict new osteoporosis susceptibility variants[121]. For example, one study predicted 37,584 new candidate osteoporosis-associated SNPs by applying a random forest model[121]. However, epigenetic regulatory analysis on GWAS variants have largely relied on reference epigenomic data (for example, NIH Roadmap Epigenomics Project) in which epigenomic profiles of each unique type of human tissues or cells were mostly generated from only one individual. Therefore, the allelic effects of GWAS variants on the inter-individual variation of cell-specific and/or tissue-specific epigenomic profiles (for example, individuals with different genotypes at a specific loci might have different levels of chromatin accessibility at the corresponding region in a specific tissue or cell of interest) are largely unknown. Future investigation with genomic and epigenomic data generated from the same set of a large number of participants should help uncover the allelic regulatory effects of osteoporosis-associated genetic variants on the epigenome.

Expression quantitative trait loci (eQTL) analysis (BOX 1) in osteoblasts[122] and osteoclasts[123] has helped to characterize the function of causal genetic variants located outside of exons and their downstream target genes in osteoporosis. For example, microarray profiles of undifferentiated osteoblasts from 95 unrelated donors of Swedish origin were used to identify eQTL for BMD GWAS[122]. Data in cultured primary osteoclasts from 158 individuals were used to identify colocalizing eQTL for genes associated with BMD[123]. Moreover, eQTL analysis on other bone-related cells and tissues, such as circulating monocytes[120], lymphocytes[124] or whole blood[124,125], have also been widely applied to decipher the regulatory roles of GWAS variants in osteoporosis. For example, lymphocytes and peripheral blood eQTL were used to identify *LINC00339* as a potentially causal gene for BMD GWAS[124]. The current sample sizes of eQTL studies on bone tissues are fairly small (<200); future studies in large samples are needed to increase the statistical power. In addition, the observed eQTL mapping on osteoporosis-associated GWAS variants might be accidental owing to high linkage disequilibrium with the true causal variant. To address this problem, several colocalization analysis approaches[126,127] have been developed to determine whether susceptibility loci identified by GWAS and eQTL share the same causal variant.

Importantly, studies in 3D chromatin interactions, which are measured by high-throughput chromatin interaction capture (known as Hi-C) analysis, have revealed a new regulatory mechanism by which functional GWAS variants could regulate distant gene expression via the formation of long-range (BOX 1) loops[6]. For example, the first Hi-C analysis in human osteoblasts and osteocytes revealed that the genes that had chromatin interactions with causal eBMD-associated variants were strongly enriched for osteocyte signature genes[6], suggesting that osteoporosis-associated genetic variants affect crucial bone-related genes by long-range regulation. A 2019 study further demonstrated that 57% of the identified chromatin interaction pairs linking osteoporosis-associated SNPs to gene promoters fell in distant genes only[128]. In one notable study, researchers found that five functional SNPs were located in an intergenic super-enhancer that could regulate the expression of *RANKL* (FIG. 3) via long-range chromosomal interactions (>100 kb)[129]. In addition, the intergenic non-coding osteoporosis-associated GWAS variant rs6426749 at 1p36.12 could regulate *LINC00339* expression via long-range loop formation (~ 360 kb)[124]. Downregulation of *LINC00339* significantly increases the expression of *CDC42* in osteoblasts, which is a pivotal regulator involved in bone metabolism[124].

When integrating multi-omics data to interpret osteoporosis GWAS susceptibility loci, the most commonly used method is to build evidence for a functional variant signal through the pairwise analyses of data sets[6,124]. Multi-dimensional methods that can analyse three or more data sets simultaneously (for example, Bayesian models[130]) will further advance our understanding of osteoporosis aetiology.

Gene and network-based studies. As genes do not function in isolation, the integration of different omics datasets at the level of genes and gene networks represents a critical approach to further increase our system-level understanding of the genetic basis of osteoporosis. For example, one group applied the weighted gene co-expression network analysis (WGCNA)[131] tool to transcriptomic expression data from bone tissues obtained from the Hybrid Mouse Diversity Panel[132] (BOX 1) and identified gene co-expression networks (termed as modules) that are highly associated with BMD[133]. From a specific BMD-associated module, they selected two 'hub' genes (that is, genes that are highly correlated with many other genes in a given module), *Maged1* and *Pard6g*, for subsequent in vitro and in vivo molecular function analyses. Specifically, knocking down the expression of *Maged1* and *Pard6g* in osteoblasts lead to altered osteoblast proliferation and differentiation, and mice deficient in *Maged1* had decreased BMD[133]. These results demonstrated the power of using a systems biology approach to discover novel genes and regulatory mechanisms involved in osteoporosis.

The network information obtained from the above analyses can be used to identify or prioritize novel disease-related genes that might not reach genome-wide significance in conventional GWAS analysis. For example, one group constructed a WGCNA network for 1,574 genes that had GWAS nominal evidence of association ($P < 0.05$) with BMD using gene expression data from transiliac bone biopsy samples obtained from 84 postmenopausal white women (39 with BMD T-score ≤ −1.0 and 45 with BMD T-score > −1.0) and discovered one module containing 44 highly interconnected genes significantly associated with BMD[134]. Further detailed submodule analyses suggested several novel candidate genes (for example, *HOMER1* and *SPTBN1*) that are important for bone metabolism[134]. *HOMER1* encodes a member of the Homer family of dendritic proteins and has an important role in glutamate signalling, which is involved in regulation of bone remodelling[135]. Interestingly, a 2017 study using a similar strategy also predicted the gene *SPTBN1* as a causal GWAS gene[51]. *SPTBN1* encodes a molecular scaffolding protein and is broadly expressed in many tissues and cell types, including high expression in osteoblasts[51]. Moreover, *Sptbn1* heterozygous knockout (*Sptbn1*$^{+/-}$) mice displayed significantly altered whole body BMD compared with the controls[51], confirming the critical role of this gene in the regulation of BMD. In addition to WGCNA, other more sophisticated algorithms for network construction and analysis of multi-omics data are quickly emerging and therefore provide exciting opportunities for future osteoporosis research[136,137].

Validation through functional studies

With numerous genes identified from GWAS, different omics studies and integrative analyses, the next step is to validate their functional roles in the pathogenesis of osteoporosis. The development of the CRISPR–Cas9 genome editing tool[138] has revolutionized molecular biology and genetics. For osteoporosis-associated gene functional studies, CRISPR–Cas9 has been used for coding-gene knockout[139], gene mutation repair[140] and validation of the effects of non-coding enhancers[124,129]. For example, CRISPR–Cas9-mediated knockouts of *DAAM2* in osteoblast cell lines resulted in a marked reduction in inducible mineralization[6].

Databases that record the consequences of disrupting each of the protein-coding genes in mice provide rich resources for validating the functional effects of candidate genes derived from GWAS and different omics studies. For example, The Origins of Bone and Cartilage Disease project, which is part of the International Knockout Mouse Consortium, aims to test over 1,600 mutant C57BL/6 strains with systemic single gene deletions for abnormalities of bone and cartilage. Although not specific to bone, similar databases, such as Mouse Genome Informatics and International Mouse Phenotyping Consortium, also provide integrated genetic, genomic and biological data to facilitate the study of osteoporosis. In addition to acting as validation resources, the identification of extreme skeletal phenotypes in mutant mouse lines in these databases can also serve as a new approach for osteoporosis-associated gene discovery[141]. For example, a 2014 study[142] analysed high-throughput screening data for 3,762 distinct global gene knockout mouse lines and identified multiple genes affecting bone mass.

Conclusions

As mentioned above, functional genomics studies of osteoporosis need to be conducted using skeletal samples and should also account for cellular heterogeneity, both of which pose obvious difficulties for human studies. The recent rapid development of single-cell omics technologies provides us with powerful new tools to individually or even simultaneously (that is, single-cell multi-omics approaches) assess various omics features at the resolution of individual cells[143], which can revolutionize our understanding of cellular heterogeneity. For example, using single-cell RNA sequencing, a 2018 study was able to successfully identify the long-sought multipotent human skeletal stem cell that exclusively differentiates into bone, cartilage and stroma but not adipose[144]. Application of the single-cell omics approaches to the field of osteoporosis research will enable us to explore known and unknown cellular heterogeneity in bone cells and tissues and dissect the cell-intrinsic and cell-specific mechanisms underlying osteoporosis.

To bridge the gap between the statistical associations and biological regulatory mechanisms, various experimental approaches can be used to test the function of osteoporosis susceptibility loci. Rather than testing the function of genetic variants one-by-one, high-throughput methods developed in 2017 (REF.[145]) (for example, massively parallel reporter assay and self-transcribing active regulatory region sequencing) can be used to examine thousands of variants in a single experiment. Applying such high-throughput methods into the post-GWAS studies of osteoporosis will lay functional evidence and mechanisms over the association results.

Another area for future osteoporosis research is the study of the human gut microbiome[146] — a number of studies in animal models[147] and humans[148] have provided compelling evidence for the importance of the gut microbiome in bone metabolism and health. With the strong interactions known to exist between the gut microbiome and the host genome[149], future host and microbiome multi-omics integration studies might lead to a major breakthrough in the prediction and therapeutic treatment of osteoporosis.

ABSTRACT

Cryptosporidium parasites are ubiquitous and can infect a broad range of vertebrates and are considered the most frequent protozoa associated with waterborne parasitic outbreaks. The intestine is the target of three of the species most frequently found in humans: *C. hominis*, *C. parvum*, and. *C. meleagridis*. Despite the recent advance in genome sequencing projects for this apicomplexan, a broad genomic comparison including the three species most prevalent in humans have not been published so far. In this work, we downloaded raw NGS data, assembled it under normalized conditions, and compared 23 publicly available genomes of *C. hominis*, *C. parvum*, and *C. meleagridis*. Although few genomes showed highly fragmented assemblies, most of them had less than 500 scaffolds and mean coverage that ranged between 35X and 511X. Synonymous single nucleotide variants were the most common in *C. hominis* and *C. meleagridis*, while in *C. parvum*, they accounted for around 50% of the SNV observed. Furthermore, deleterious nucleotide substitutions common to all three species were more common in genes associated with DNA repair, recombination, and chromosome-associated proteins. Indel events were observed in the 23 studied isolates that spanned up to 500 bases. The highest number of deletions was observed in *C. meleagridis*, followed by *C. hominis*, with more than 60 species-specific deletions found in some isolates of these two species. Although several genes with indel events have been partially annotated, most of them remain to encode uncharacterized proteins.

immunocompromised patients. It is also a cause of death in children under 24 months old, especially in low-income countries (Sow et al., 2016; Troeger et al., 2017). Furthermore, *Cryptosporidium* is the most frequent protozoa associated with waterborne parasitic outbreaks worldwide (Efstratiou, Ongerth & Karanis, 2017).

Cryptosporidium is classified as a gregarine, within its subclass, the Cryptogregaria (Ryan et al., 2016). Thus far, there are at least 39 species established, and more than 30 genotypes (Firoozi et al., 2019). Among them, approximately twenty-one have been found in humans. However, *Cryptosporidium hominis* and *Cryptosporidium parvum* are responsible for more than 90% of the reported human infection cases worldwide (Grinberg & Widmer, 2016; Feng, Ryan & Xiao, 2018). Other species, occasionally described in humans, including *C. meleagridis*, *C. felis*, *C. canis*, *C. ubiquitum*, *C. cuniculus*, *C. viatorum*, *C. muris*, chipmunk genotype I, *C. andersoni*, *C. suis*, *C. bovis*, horse genotype, *C. xiaoi*, skunk genotype, mink genotype, *C. erinacei*, *C. fayeri*, *C. scrofarum* and *C. tyzzeri* (Feng, Ryan & Xiao, 2018). These species and genotypes differ significantly in human infectivity, host range, geographic distribution, and virulence (Camaa et al., 2007; Cama et al., 2008; Adamu et al., 2014; Feng, Ryan & Xiao, 2018). Some species, such as *C. hominis*, have very narrow host ranges, mostly restricted to humans, nonhuman primates, and horses, whereas others, such as *C. parvum*, have a broad host range, infecting ruminants, horses, rodents, and other animals besides humans (Ryan, Fayer & Xiao, 2014). *Cryptosporidium meleagridis*, which is the third most prevalent species in humans, has been described in mammals and birds (Stensvold et al., 2014).

Cryptosporidium molecular phylogeny and evolutionary relationships have been studied through PCR of single or multiple genetic markers (Feng et al., 2007; Xiao, 2010; Xiao & Feng, 2017; Cunha, Peralta & Peralta, 2019). *Cryptosporidium* species identification protocols usually include the amplification and sequencing of the small subunit (SSU) rRNA gene. Additionally, glycoprotein 60 gene (gp60) has been used to study subtypes and intra-species diversity of the genus, leading to the currently accepted classification into gp60 allelic families subtypes (Xiao, 2010). The SSU rDNA gene in *Cryptosporidium* species does not evolve under a neutral model, and its genetic diversity is restricted to a few polymorphic sites (Sulaiman, Lal & Xiao, 2002). Additionally, some species appear to evolve much quicker than others, according to the SSU rDNA locus.

Regarding the gp60 gene, its high genetic diversity has been attributed to the action of positive selective pressure. Because it can be exchanged by genetic recombination, its typing information does not always agree with other loci, especially with some *C. parvum* subtype families (Feng, Ryan & Xiao, 2018). Other loci used in the *Cryptosporidium* typing include coding genes of actin, 70 kDa heat-shock protein (HSP70), and the *Cryptosporidium* oocyst wall protein (COWP) (Cunha, Peralta & Peralta, 2019). Most of these loci do not evolve neutrally, and the rate of evolution may vary among the different species of the genus (Sulaiman, Lal & Xiao, 2002). According to the above, phylogenetic inference based on analysis of one or a few genetic loci, some under selection pressure, might not reflect the real phylogenetic relationships at the whole genome level (Sulaiman, Lal & Xiao, 2002; Morris et al., 2019).

The growing use of whole-genome shotgun sequencing (WGS) and next-generation sequencing (NGS) in the study of *Cryptosporidium* spp. is allowing better phylogenetic and comparative genomic analysis within the genus (*Widmer & Sullivan, 2012*; *Mazurie et al., 2013a*; *Guo et al., 2015*; *Isaza et al., 2015*; *Ifeonu et al., 2016*; *Beser et al., 2017*; *Sikora et al., 2017a*; *Feng et al., 2017*; *Khan, Shaik & Grigg, 2017*; *Gilchrist et al., 2018*; *Fan, Feng & Xiao, 2019*; *Xu et al., 2019*; *Nader et al., 2019*). The first *Cryptosporidium* genomes were generated in 2004 using capillary sequencing, belonging to the *C. parvum* (Iowa strain) and *C. hominis* (TU502 strain) species (*Xu et al., 2004*; *Abrahamsen, 2004*). Since then, high-quality (NGS-based) genomes from several subtypes of these species and other human-related species are increasingly available (*Widmer & Sullivan, 2012*; *Mazurie et al., 2013a*; *Guo et al., 2015*; *Beser et al., 2017*; *Feng et al., 2017*; *Sikora et al., 2017a*; *Gilchrist et al., 2018*; *Nader et al., 2019*; *Xu et al., 2019*). Comparative analysis shows a remarkable structural and compositional conservation in genome organization among intestinal *Cryptosporidium* species (*Fan, Feng & Xiao, 2019*). The genome size is near 9.0 Mb in length and is arranged into eight chromosomes, with perfect synteny (no evidence of genome rearrangements), extremely compact coding genes, and a low number of gene introns (*Fan, Feng & Xiao, 2019*). It has been postulated that the phenotypic differences between *Cryptosporidium* species could be associated with minor sequence variations (single nucleotide variants-SNVs and short indels) that can affect expressed proteins or gene regulation patterns (*Guo et al., 2015*; *Feng et al., 2017*; *Sikora et al., 2017a*; *Gilchrist et al., 2018*; *Su et al., 2019*; *Xu et al., 2019*). Nonetheless, several studies have demonstrated events of major insertions and deletions between several species of *Cryptosporidium*, usually involving members of multicopy gene families under positive selection, such as those located near telomeres, like the MEDLE proteins, insulinase-like proteases, and mucin-type glycoproteins. These genes have been associated with the host-parasite interaction (*Guo et al., 2015*; *Feng et al., 2017*; *Gilchrist et al., 2018*; *Xu et al., 2019*).

Molecular phylogenetic strategies have been developed to understand the evolutionary relationships between proteins or genes and help to unravel the evolutionary history of the species. Phylogenetic analysis can also give insights into epidemiological, immunological, and evolutionary processes shaping genetic variation in natural populations of the parasite, and may even have the potential to improve future public health measures (*Baele et al., 2017*; *Theys et al., 2019*). Although phylogenomics studies on apicomplexan parasites are scarce, in models such as Piroplasmida and Haemosporida, they have been useful in the elucidation of the taxonomy and phylogenetic relationships within these protozoa, through the incorporation of a broad number of taxons and DNA datasets (*Cornillot et al., 2012*; *Lack, Reichard & Van Den Bussche, 2012*; *Galen et al., 2018*).

Here we used a comprehensive phylogenomic approach to have a better view of the evolutionary relationships of the three most relevant human infecting species of *Cryptosporidium* protozoan parasites (*C. parvum*, *C. hominis*, and *C. meleagridis*), including genomes with different subtype families. Furthermore, a detailed comparative analysis of the largest indel events detected in these three species is presented, which allowed a more comprehensive view of the gene content differences among these three apicomplexan species.

METHODS

NGS data and assembly

Read sequences were downloaded from the Sequence Read Archive - SRA of the NCBI public database. Reads of 23 genomic projects of three *Cryptosporidium* species were included: *C. parvum, C. hominis,* and *C. meleagridis*. Four genomes of *C. meleagridis*, ten genomes of *C. hominis,* and nine genomes of *C. parvum*, including the *C. parvum* anthroponotic isolates UKP14 and UKP15 were analyzed. The reads were extended using FLASH v1.2.11 (*Magoc & Salzberg, 2011*); then the extended and independent read pairs were assembled with the software SPADES v3.11.1 (*Bankevich et al., 2012*), with default settings and testing k-mers of 33, 55, 77, 99, and 111 bases; then the descriptive statistics of the assembly were calculated with in house Perl scripts. To avoid any possible contamination of the sequences with other species, the assembled contigs were aligned using BLASTN with the reference genomes (chromosomes) of *C. hominis* UdeA01, *C. parvum* Iowa II and *C. tyzzeri* UGA55, downloaded from CryptoDB v43 (*Puiu, 2004*). The contigs with a Bit score value ≥ 300 were kept for further analyses.

Sequencing depth analysis

All the reads were mapped against the *C. parvum* Iowa II reference genome downloaded from CryptoDB v43 and against the *de novo* assembled contigs using BWA (*Li & Durbin, 2010*) with default options. Then, the Samtools-depth tool (*Li et al., 2009*) was used to compute the read depth at all positions, with a maximum coverage depth to 1,000,000. Finally, the mean coverage was estimated in the Linux terminal with an awk formula.

Single nucleotide variants detection

Detection of SNVs was performed aligning with MUMmer v3 the assembled scaffolds for each isolate with the *C. parvum* Iowa II reference genome. Then, the MUMmer function show-SNPs, and dnaDIFF tools were used (*Delcher et al., 2002*).

Phylogenomic analysis

The phylogenomic analysis was performed based on the SNVs found within the 24 selected *Cryptosporidium* genomes. A matrix comprising all the SNVs detected was constructed and loaded into the program IQ-TREE v1.6.12 (*Trifinopoulos et al., 2016*). A maximum-likelihood (ML) tree (*Felsenstein, 1981*) was built using this phylogenomic inference software. Modelfinder was used to select the best model of evolution under Bayesian Information Criterion (BIC) (*Schwarz, 1978*). Transversion Model TVM (TVM+F+ASC+R2) was selected as an evolutionary model. Branch support was estimated using 1000 iterations of the Shimodaira-Hasegawa test (SH -aLRT) (*Shimodaira & Hasegawa, 1999*),Shimodaira Hasegawa 1000 pseudoreplicates of ultra-fast bootstrap (*Hoang et al., 2018*). The presented tree is unrooted, and the longest branch was selected as an arbitrary outgroup. The tree was edited using FigTree v1.4.4 (*Andrew, 2018*).

Identification of SNVs in coding regions

For the detection of single nucleotide variants in the CDSs, the reads were mapped to the genome of *C. parvum* Iowa II with the BWA (Burrows-Wheeler Aligner) aligner version

0.7.17 (*Li & Durbin, 2010*). Later, the bam and VCF files were generated with SAMtools and BCFtools, respectively (*Danecek et al., 2011*). Only variants with a Phred quality score $\geq$ 50 (*Holder et al., 2013*) were included. Finally, the SAMtools Depth tool was used to calculate the reading depth at all positions, with a maximum coverage depth of 1,000,000. Subsequently, the mean coverage was estimated with an awk formula. The single nucleotide variants in CDSs were annotated with the effect predictor SIFT4G (sorting intolerant from tolerant) version 3.0 (*Vaser et al., 2016*).

Identification of insertions and deletions

Insertions and deletions –indels - were identified with MUMmer aligner (Maximal Unique Matches) version 3.0 (*Delcher et al., 2002*), as previously described by *Isaza et al. (2015)*, excluding those with a length <50 nucleotides with the software online Assemblytics (*Nattestad & Schatz, 2016*). To perform the functional analyzes, the genome of *C. parvum* Iowa II version 43 deposited in CryptoDB (*Puiu, 2004*) was used as a reference. Variants were initially detected in coding regions, and then genes with shared and species-exclusive deleterious mutations were identified and annotated.

Identification and annotation of genes with deleterious non-synonymous changes

From the prediction obtained with SIFT4G, genes with deleterious mutations in the eight chromosomes were filtered for each of the genomes. These genes were extracted with the SeqSelect.py script, and enrichment analysis in Gene Ontology terms was performed with the EggNOG mapper program version 1.0 (*Huerta-Cepas et al., 2017*); and visualization with WEGO (Web Gene Ontology Annotation Plotting) version 2.0 was done (*Ye et al., 2018*). Then, functional orthology analysis was performed with KEGG on the KAAS server (*Ogata et al., 1999*), selecting the best hits using a bidirectional strategy - BBH (bi-directional best hit). To detect genes with transmembrane domains, the TMHMM version 2.0 server (*Krogh et al., 2001*) was used. Prediction of the genes that code for proteins with classical and non-classical secretion was performed with the online servers SIGNALP version 5.0 (*Almagro Armenteros et al., 2019*) and SECRETOME-P version 2.0 (*Bendtsen et al., 2004*), respectively.

RESULTS

Selected *Cryptosporidium* genomes

To carry out a comprehensive genomic comparative analysis, we chose all the NGS projects of the three main species of *Cryptosporidium* that infect humans (*C. hominis, C. parvum,* and *C. meleagridis*), that have raw sequence data available in public databases. A total of 23 genomes were included: ten isolates of *Cryptosporidium hominis* (UKH1, UKH3, UKH4, UKH5, 37999, TU502_2012, 30976, UdeA01, SWEH2, and SWEH5); nine isolates of *C. parvum* (UKP2, UKP3, UKP4, UKP5, UKP6, UKP7, UKP8, and the *C. parvum* anthroponotic isolates UKP14 and UKP15); and four isolates of *C. meleagridis* (UKMEL1, UKMEL3, UKMEL4, and TU1867). The low representation of *C. meleagridis* genomes is due to the limited number of sequencing projects for this species, so all available genomes in public databases until September 2019 were included. The genomes belong to different gp60 subtypes, and the majority comes from the UK. All the studied genomes come from parasite oocysts isolated from human feces of patients with natural infections, and four of these were maintained through passages in piglets, mice, or chickens. Most genomes were sequenced on Illumina's HiSeq and MiSeq platforms, and only two (*C. hominis* SWEH2 and SWEH5) used the Ion Torrent platform (Table S1).

De novo genome assembly analysis

The raw read data of the 23 selected genomic projects were downloaded from the Sequence Read Archive - SRA of the NCBI public database and assembled with SPAdes. If the isolate had assembly data available, the metrics of the two assemblies were compared, and the contig set that showed the better N50 value was kept for further analysis. Only six genomes of the studied had better N50 values than our assemblies. All of them were deposited at the CryptoDB database v43: *C. hominis*: UKH1, TU502_2012, 30976, 37999, UdeA01, and *C. meleagridis* UKMEL1 (Table S2). Only for three genomes, it was not possible to find a previous assembly data available: *C. hominis* (SWEH2 - SWEH5) and *C. meleagridis* (TU1867). To exclude possible contaminating contigs, BLASTN comparisons with a *Cryptosporidium* genome database (reference genomes of *C. hominis* UdeA01, *C. parvum* Iowa II and *C. tyzzeri* UGA55) were performed, and only those with Bit score value ≥ 300 were kept for further analyses. Selected genomes assemblages' statistics are also shown in Table S2.

Cryptosporidium genome size is close to 9.0 Mb in most studied isolates; only three have genome assemblies below 9.0 Mb; 8.2 Mb, in *C. parvum* anthroponotic UKP14, and 8.8 Mb in both *C. hominis* SWEH2 and SWEH5 isolates. Four genomes had a mean read coverage below 50X, three of which belong to *C. hominis* species (UKH3, SWEH2, and SWEH5) and the *C. parvum* isolate UKP5. The most fragmented genomes were in the *C. parvum* species, isolate UKP3 and the anthroponotic UKP14 with 2,971 and 2,787 contigs, respectively, with coverage above 229X and 69X. All genomes have an average GC content of 30% and ambiguities that do not exceed 0.26% (Table S2).

Single nucleotide variants detection

To identify single nucleotide variants -SNVs- throughout the genomes, inter and intra-species comparisons were made aligning the *de novo* assembled contigs of each isolate against the reference genome of *C. parvum* Iowa II. *Cryptosporidium parvum* isolates aligned more than 99.2% of the contig bases to the Iowa reference, except for the anthroponotic genomes, UKP14 and UKP15, that aligned 97%. *C. hominis* genome data behave similarly, with an aligned ratio that ranges between 99 to 99.38%, except for UKH4 that reached 98%. In *C. meleagridis*, a lower alignment rate was achieved with an overall rate close to 97% (Table S3).

The global nucleotide identity showed the expected results based on the phylogenetic relationship among the three species. While *C. parvum* genome identity ranged between 99.51% and 99.93% within the species, *C. hominis* genomes showed an identity of around 96.8% compared to the Iowa reference genome. *Cryptosporidium meleagridis* confirmed its higher distance with *C. parvum* with a global identity of around 91.5%.

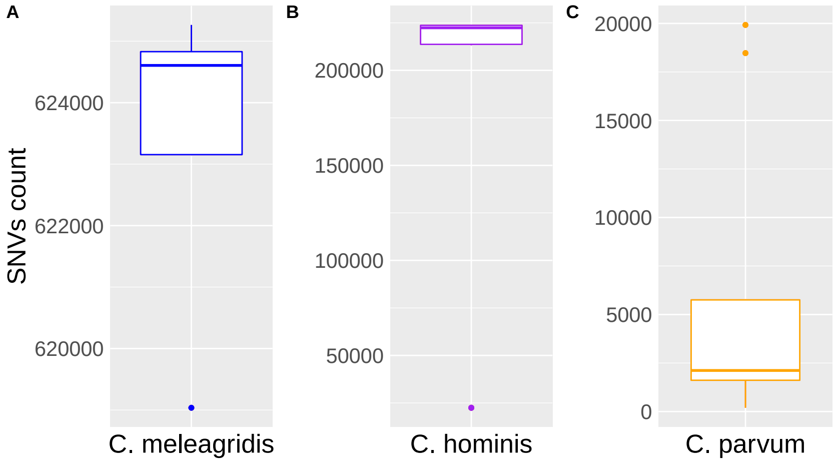

Figure 1 **Accumulation of SNVs in Cryptosporidium species.** Box plots of the *Cryptosporidium* species analyzed and the number of total SNVs detected. The medians of the SNVs found in each species are (A) *C. meleagridis* (624,607), (B) *C. hominis* (223,640), and (C) *C. parvum* (2,116). Outliers in *C. meleagridis* and C. hominis correspond to the UKMEL3, SWEH2, and SWEH5, respectively. Concerning *C. parvum*, outliers correspond to anthroponotic UKP14 and UKP15 isolates.

Full-size 🖼 DOI: 10.7717/peerj.10478/fig-1

Single nucleotide variants within the *C. parvum* genomes ranged between 1,595 and 5,752, except for the anthroponotic isolates that showed more than 18,000 SNVs. When *C. hominis* genomes were compared with the *C. parvum* Iowa II reference, around 220,000 SNVs were detected in each isolate, while in *C. meleagridis* genomes, the number when up to more than 600,000 (Fig. 1).

Phylogenomic analysis

To verify the topology and taxonomic location described in the genus *Cryptosporidium*, the SNV data was used to generate a nucleotide matrix. Then, an unrooted maximum likelihood (ML) tree was constructed, including the 24 evaluated genomes (23 de novo assembled genomes and the reference genome Iowa II). The transversion model (TVM) was selected as the best model of evolution Table S4). The complete matrix comprised 800,861 sites and the best tree had had a likelihood value of −3401691.458. The tree obtained shows three monophyletic clades, following the actual classification scheme, that group the 24 genomes of the three *Cryptosporidium* species included in this work. The branch supports are optimal and have a 100% agreement between SH-aLRT and ultra-fast bootstrap for the main branches, with discrepancies in three internal *C. parvum* nodes and one internal *C. hominis* node (Fig. 2).

Within the *C. parvum* species, the presence of two separate branches with statistical supports was observed, which allowed the segregation of the anthroponotic isolates UKP14 and UKP15 in a separate branch of the zoonotic isolates with a 100% support. Furthermore, it is noteworthy to point out that all the *C. parvum* isolates that belong to the gp60 gene IIa subtype family grouped with a 100% bootstrap, including the isolate Iowa II. In the case of *C. hominis* clade, the isolates seem to segregate with statistical support according to its subtype family, except for isolate 30976. The *C. meleagridis* clade is also supported with

Figure 2 **Phylogenomic analysis of *Cryptosporidium* species.** Maximum Likelihood (ML) tree was based on the SNVs present within the 24 *Cryptosporidium* genomes studied. The presented tree is unrooted, and the longest branch was selected as an arbitrary outgroup. The horizontal scale line represents the number of base substitutions per site analyzed. TVM was the evolutionary model. The supports of the branches are based on an analysis of 1000 **aLRT** replications (%) / ultra-fast **bootstrap** replications (%). Red branches have an aLRT and bootstrap value of 100%. Branches are labeled with the isolate ID and allelic family based on the *gp60* gene.

Full-size DOI: 10.7717/peerj.10478/fig-2

100% bootstrap, and the phylogenetic signal is enough to separate the 4 different isolates according to its subtype family. In general, all genomes were grouped according to the species classification and its gp60 gene subtype family (Fig. 2).

Single nucleotide variants in coding regions

SNVs located in coding regions were identified in all the genomes through the read mapping analysis against the *C. parvum* Iowa II version 43 of CryptoDB. As expected, compared with the *C. parvum* IOWA reference, the genomes of *C. hominis* and *C. meleagridis* showed the highest number of these variants in coding regions with more than 150,000 and 400,000, respectively, and nearly 60% corresponding to synonymous changes (sSNVs). There were no intraspecies differences in the accumulation of variants in coding regions or synonymous and non-synonymous changes in both species. On the contrary, in *C. parvum* isolates, the number of SNVs in CDSs was less than 20,000 in all genomes, with more than 50% corresponding to non-synonymous mutations. The results in *C. parvum* suggest an

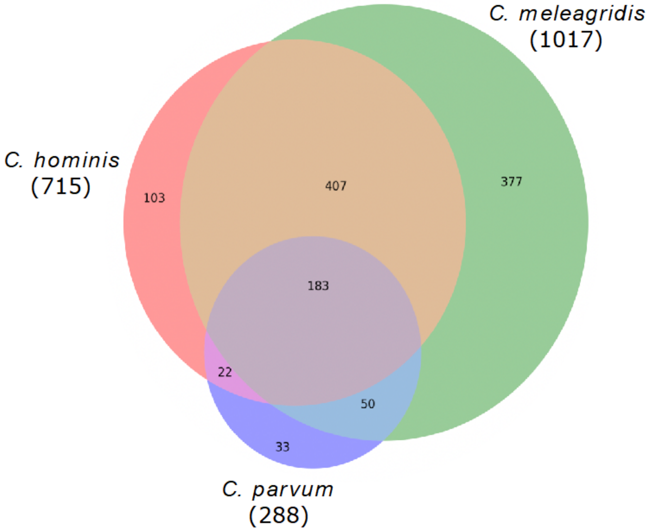

Figure 3 **Genes detected with deleterious mutations in the three *Cryptosporidium* species.** Venn diagram showing the genes with shared and exclusive deleterious mutations in the three *Cryptosporidium* species included in the study.

Full-size 🖼 DOI: 10.7717/peerj.10478/fig-3

intraspecies heterogeneity with values ranging between 840 and 3,476 SNVs in CDSs in zoonotic isolates and around 14,000 in anthroponotic isolates. However, these differences were not statistically significant. After characterizing the synonymous and non-synonymous mutations in coding regions, the genes with nsSNVs were analyzed separately, finding 2,532 in at least one genome of each species, with 110 exclusives for *C. meleagridis*, 11 for *C. hominis,* and 2 for *C. parvum*.

Genes with non-synonymous variants (nsSNVs) were annotated by the SIFT4G effect predictor, and those with non-tolerated changes and possibly associated with deleterious mutations were identified. With this strategy, a total of 1,017 genes were predicted with deleterious mutations in *C. meleagridis*, 715 in *C. hominis,* and 288 in *C. parvum*. Of these, 183 are shared by all three species, being present in at least one genome of each species; 377 are exclusive to *C. meleagridis*; 103 to *C. hominis,* and 33 to *C. parvum* (Fig. 3).

Only 29.5% of the genes annotated with deleterious mutations by SIFT, and shared by the three species, could be annotated with EggNOG mapper. Enrichment analysis in GO terms indicated that they are mainly involved in biological processes and metabolic processes with molecular functions such as catalytic or binding activity.

The functional orthology analysis performed on the KAAS server against the KEGG database had a better performance compared to the previous GO assignment, annotating 46.5% of the shared genes and indicating that most of them are involved in enzymatic processes, DNA repair, recombination, and proteins associated with the chromosomes (Fig. 4). Complementary annotation determined that only 1.1% of the genes encoded proteins secreted by the classical pathway, whereas 10.9% encoded for proteins secreted

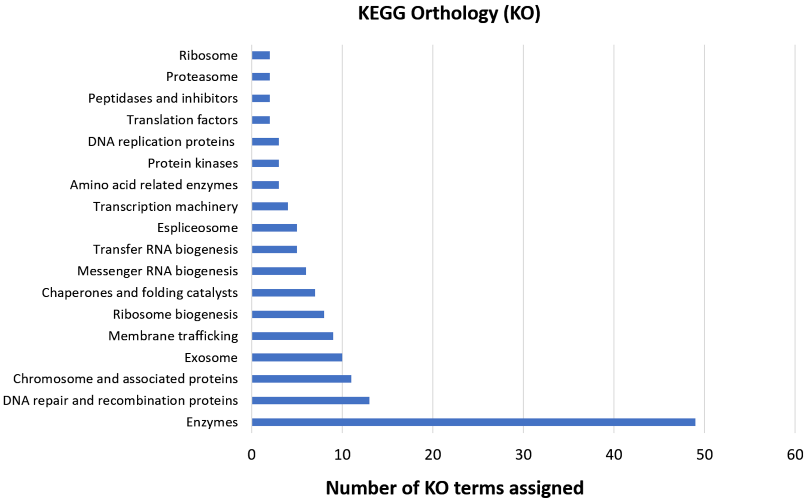

Figure 4 **KEGG orthology analysis of genes with deleterious mutations shared by the three *Cryptosporidium* species.** Assignment of KO terms to genes with deleterious mutations detected in the three *Cryptosporidium* species through the KAAS server in the KEGG database.

Full-size DOI: 10.7717/peerj.10478/fig-4

by non-classical systems. Additionally, 2.3% of the putative encoded proteins exhibited domains with transmembrane helixes.

Regarding genes that carry deleterious mutations within each species (species-specific mutated genes), 29.1 and 28.9% were classified in at least one GO category for *C. hominis* and *C. meleagridis*, respectively. In *C. parvum*, GO terms were assigned only in 3 genes (9.09%), classified exclusively in the cellular component category. The functional orthology analysis again achieved a better result compared to the EggNOG-mapper software, assigning 42.4% in *C. parvum* (Fig. 5A), 60.2% KO in *C. hominis* (Fig. 5B), and 59.1% in *C. meleagridis* (Fig. 5C). The assignment of functional orthologs in metabolic pathways established that in the three species, most of these genes are involved in enzymatic processes. The second most frequently assigned pathway in genes with species-exclusive deleterious mutations was ribosome transfer RNA biogenesis in *C. parvum*, spliceosome complex in *C. hominis*, and biogenesis in *C. meleagridis*.

Indel events analysis

Inter and intraspecies indel events were identified in the genomes through their comparison to the *C. parvum* Iowa II reference genome. For simplicity reasons, insertions and deletions were referred, assuming as reference the *C. parvum* Iowa II genome. Observed insertions were in the range of 50 to 500 nucleotides. In *C. parvum*, the highest number of insertions was detected in the zoonotic isolates UKP3 and UKP4. No statistically significant differences were found in the accumulation of insertions among the studied species. Deletions identified in the genomes had a similar size to that described for the insertions, with the majority falling into the range of 50 to 500 nucleotides. The highest number was observed in the genomes of *C. meleagridis*, followed by *C. hominis*. However, no significant differences were found in the accumulation of deletions among species.

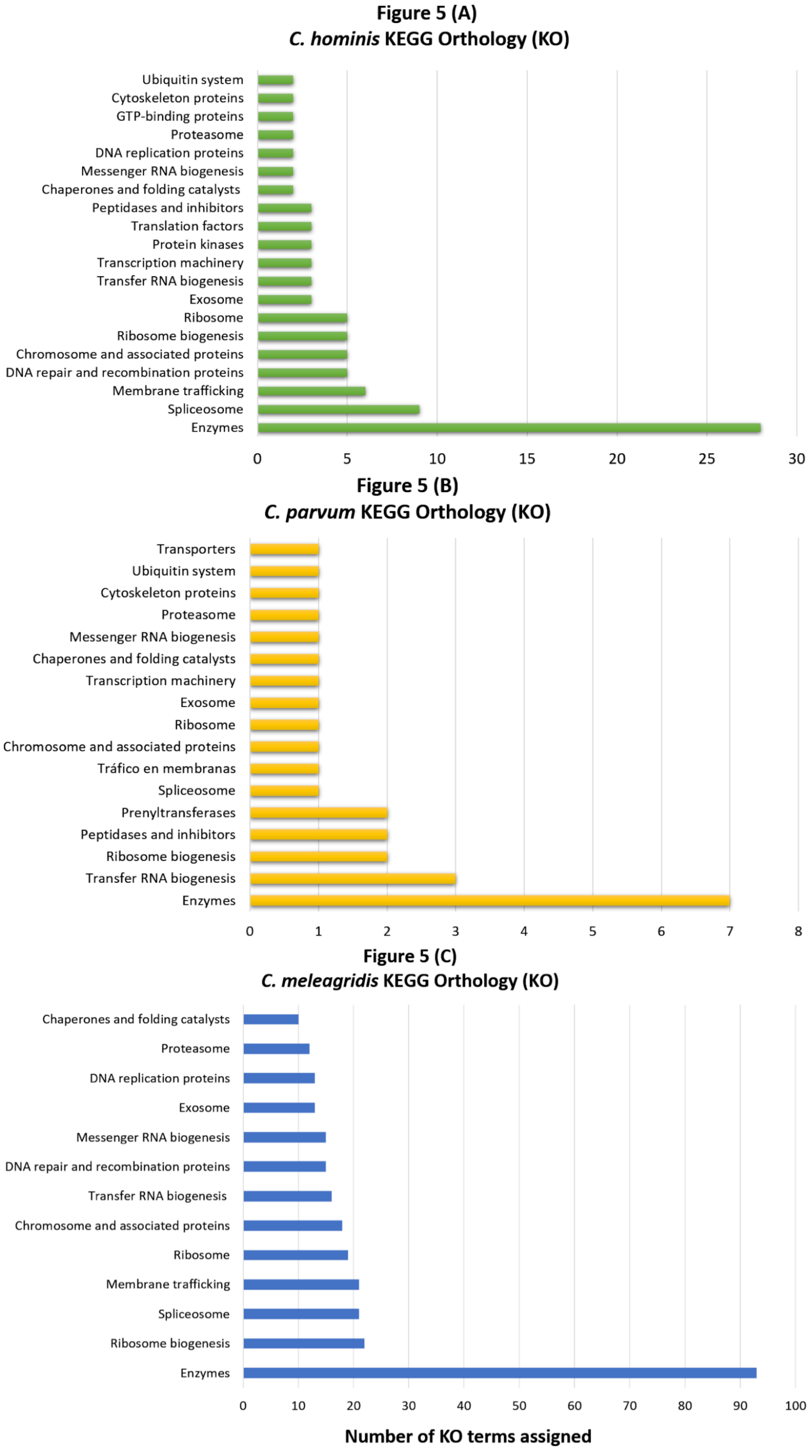

Figure 5 **KEGG orthology analysis of genes with species-exclusive deleterious mutations.** Assignment of KO terms to genes with species-exclusive deleterious mutations via the KAAS server in the KEGG database in *C. hominis* (A), *C. parvum* (B), and *C. meleagridis* (C).

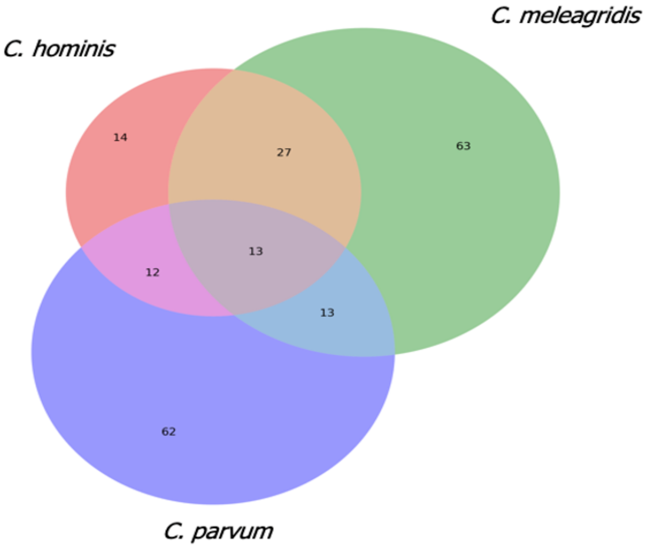

Figure 6 **Analysis of genes with indel events in the three *Cryptosporidium* species.** Venn diagram that shows the genes with indel events that are shared and exclusive in the three *Cryptosporidium* species.
Full-size DOI: 10.7717/peerj.10478/fig-6

Coding genes that presented indels in the three species were identified and annotated, whenever possible. We found 322, 215, and 176 genes with indels in *C. hominis*, *C. parvum*, and *C. meleagridis*, respectively, but only 13 were common to all 23 *Cryptosporidium* isolates. In both *C. meleagridis* and *C. hominis*, deletions were the most frequent indel event, corresponding to 76.1% and 59% of all structural variants, respectively. The *C. hominis* isolates UKH4 was the exception, in which insertions predominated. In contrast, in *C. parvum*, deletions were less common, representing 38% of the structural variants detected in the CDSs.

To gain insights into the gene losses occurring in the 23 isolates, those genes with indel events present in at least two genomes/isolates in each species were characterized. A total of 116 genes were selected in *C. meleagridis*, 100 in *C. parvum*, and 66 in *C. hominis*. Sixty-three were exclusive to *C. meleagridis*, 62 to *C. parvum*, and 14 to *C. hominis* (Fig. 6).

According to the annotation deposited in CryptoDB Version 46, of the 13 genes with insertion and deletion events shared by the three species, 40% code for uncharacterized proteins and the remaining for hydrolases (cgd8_1220), proteins with recognition motifs of RNA (cgd3_4150), mucins (cgd7_4020), among others. Twenty-seven genes with indels were identified in all *C. meleagridis* genomes, with 56% of them corresponding to uncharacterized proteins. Regarding *C. parvum*, insertions in the genes cgd3_190 (involved in the formation of fibrillin) and cgd3_3900 (uncharacterized protein) were present in 56% of the evaluated genomes. An interesting finding was that all *C. hominis* genomes exhibited indels in three genes (orthologs of cgd6_4290, cgd7_420, and cgd7_500); with cgd6_4290 and cgd7_420 being also affected in all genomes of *C. meleagridis* (Table S5).

DISCUSSION

Advances in DNA sequencing technologies and bioinformatics have promoted the routine use of complete genome sequences, revolutionizing the study of both model and non-model organisms, particularly in microbiology (*Young & Gillung, 2020*). Phylogenomic is one of the numerous disciplines that have taken advantage of the progress in NGS technologies, using the massive datasets to infer both phylogenetic relationships between taxa, improving the understanding of molecular evolution, and putative functions for DNA or protein sequences (*Young & Gillung, 2020*).

A phylogenomic analysis is being applied now to validate previous findings with classic single-marker molecular methods and to resolve with unprecedented resolution, the phylogenetic relationships between species and isolates of the human infecting *Cryptosporidium* parasites (*Glaberman et al., 2001*; *Abe & Makino, 2010*; *Abal-Fabeiro et al., 2013*; *Wagnerová et al., 2015*; *Pérez-Cordón et al., 2016*). However, this phylogenomic approach has focused on *C. hominis* and *C. parvum* by studying multiple concatenated loci (*Feng et al., 2017*; *Nader et al., 2019*), or different variable positions that represent below 1% of the genome (*Gilchrist et al., 2018*). To gain insights into the evolutionary relationships in *Cryptosporidium,* a comparative and phylogenomic study was conducted with 23 genomes of the most frequent species in humans: *C. hominis*, *C. parvum*, and *C. meleagridis*.

The sequence identity between *C. hominis* genomes (96.85%) and the reference genome of *C. parvum* Iowa II found in our study confirms the high similarity between both species and agrees with previous findings that report differences of a maximum of 3% (*Xu et al., 2004*; *Mazurie et al., 2013b*; *Zahedi et al., 2013*). These studies describe that both genomes exhibit remarkable structural conservation, and some authors suggest that the phenotypic differences may be due to subtle variations in the sequences of genes that code for the interface proteins between the parasite and its host (*Xu et al., 2004*; *Mazurie et al., 2013b*; *Zahedi et al., 2013*). Regarding *C. parvum*, there was a lower percentage of aligned blocks against the reference genome in the anthroponotic isolates compared to the zoonotic ones, which agrees with other studies that have also described differences in the genomic structure and nucleotide content between zoonotic and anthroponotic isolates of *C. parvum* (*Widmer et al., 2012*; *Fan, Feng & Xiao, 2019*; *Nader et al., 2019*). As it was expected, *C. meleagridis* genomes had a lower global identity against *C. parvum* reference genome than that detected with *C. hominis*, which agrees with the phylogenetic relationships described for the three species using different genetic locus (*Šlapeta, 2013*; *Khan, Shaik & Grigg, 2017*). This finding may be related to the differences in host specificity reported in the three species, where *C. hominis* and *C. parvum* have host ranges limited to mammals, while *C. meleagridis* is described in mammals and birds (*Šlapeta, 2013*; *Khan, Shaik & Grigg, 2017*). It has been suggested that mammals were possibly the original hosts for *C. meleagridis* and that later this species adapted to birds (*Caccio & Widmer, 2014*).

Single nucleotide variants (SNVs) results obtained in this study showed similar behavior in their number and frequency in the genomes of *C. hominis* with around 220,000 variants, compared to the *C. parvum* IOWA reference, results that differ from those reported in previous comparative studies (*Isaza et al., 2015*; *Gilchrist et al., 2018*). Isaza et al. (*Isaza et al., 2015*) identified an average of 43,258 SNVs between the reference genome *C. parvum* Iowa II and the *C. hominis* UdeA01, UKH1, and TU502_2012 isolates (deposited in CryptoDB version 8). One possible explanation of the lower number of SNVs detected in this work could be the different methodological approaches used to identify these variants. Authors only considered those SNVs located at 30 nucleotides or more from regions where the alignment failed, underestimating the total number of SNVs. Additionally, the genomes used in Isaza's study were obtained from the CryptoDB version 8 database, whose genomes had a lower degree of purification than those used in our work (version 43). *Gilchrist et al. (2018)* also found a lower number of SNVs (36,780) in a comparative study of 32 genomes of *C. hominis*. The authors mapped the short reads of the *C. hominis* genomes against the genome of *C. parvum* Iowa, which was sequenced with Pacific Biosciences (PacBio). It could be possible that the assembly of a genome through long sequencing reads can affect the number of variants detected. Although it is not clear how long reads sequencing methods might differ from comparative genomic approaches using short-read data, i.e., Illumina (*DeMaio et al., 2019*), it has been shown that error rates on this platform are much higher than those recorded for Illumina (15% versus 0.1%) and usually is performed at a lower read coverage compare to Illumina projects.

Concerning the single nucleotide variants among the *C. parvum* genomes evaluated in this study, a more significant number of SNVs was identified in the anthroponotic isolates with more than 18,000 compared to the zoonotic isolates, which ranged between 1,595 and 5,752 SNVs. These results are similar to the findings reported by *Widmer et al. (2012)*, who identified about 16,606 SNVs by comparing the genomes of two *C. parvum* isolates with different host ranges, the anthroponotic *C. parvum* TU114 and the reference genome of the zoonotic Iowa II isolate. The differential accumulation of intragenotypic SNVs in *C. parvum* reflects the genetic diversity of this species, which is possibly related to the evolution of the parasite influenced by the selective pressures in both humans and animal hosts. For this reason, it has been postulated that the accumulation of genomic variants could influence the host range (*Weir et al., 2011*; *Blake et al., 2015*; *Grinberg & Widmer, 2016*). Concerning *C. meleagridis*, more than 600,000 SNVs were identified in the genomes compared against the reference genome of *C. parvum*. It is essential to highlight that there are currently no reports on the structural variations like SNVs in this species, being this the first one.

In this work, a comprehensive phylogenomic analysis using more than 800.000 single nucleotide variations detected in 24 genomes of the species *C. parvum*, *C. hominis,* and *C. meleagridis* was done. To our knowledge, this is the most extensive phylogenomic analysis carried out within the genus and one of the largest within the Phylum Apicomplexa. One of the main findings in this study is that, although we didn't select neutral evolving positions within the genomes, there was a strong phylogenetic signal, supported by two statistical tests, that allowed the well-supported segregation for most of the isolates. However, discrepancies were found in three internal *C. parvum* nodes and one in *C. hominis*. It is essential to highlight that the mentioned differences did not alter the global topology of the phylogenomic tree obtained. In related literature, it has been described that the mismatches in the supports of the branches obtained by bootstrapping and probability ratio tests can arise as a consequence of performing the analysis with small samples and with highly heterogeneous nucleotide substitution models (Guindon et al., 2010).

The obtained tree confirms the previously reported topology for these three intestinal species of *Cryptosporidium*, inferred from single-locus phylogenetic studies, and by the use of different loci such as 18S rRNA, gp60, and other polymorphic genes (Ren et al., 2012; Šlapeta, 2013; Nader et al., 2019). *Cryptosporidium meleagridis* is confirmed as the most divergent group among the three studied species (Šlapeta, 2013; Khan, Shaik & Grigg, 2017). At the species rank, the bootstrap and SH-aLRT statistical support was 100%. Furthermore, most of the isolates were grouped according to its *gp60* gene family type, regardless of its geographical origin.

The phylogenomic analysis of the *C. parvum* isolates evidenced the separation of its central clade into two branches with significant statistical support (100%), with zoonotic isolates in one branch and anthroponotic isolates in the other. This finding agrees with that reported by several authors (Widmer et al., 2012; Danišová et al., 2017; Feng et al., 2017; Nader et al., 2019), in which through unilocus phylogenetic analyzes and multiple concatenated loci between anthroponotic and zoonotic isolates, determined that the anthroponotic isolates of *C. parvum* formed a separate group from the zoonotic isolates. Nader et al. (2019), through phylogenetic analysis of neutrally evolving coding loci across 21 *Cryptosporidium* isolates, identified two *C. parvum* lineages with distinct host-specificity, which were designated as *Cryptosporidium parvum parvum (* zoonotic) and *C. p. anthroponosum* (anthroponotic). Additionally, they found that human infective *C. hominis* and *C. parvum* isolates form a distinct superclade along with *C. cuniculus*, another species associated with human infections. Subsequent analysis of high-quality SNPs detected in 16 genomes of the two *Cryptosporidium parvum* subclades, confirming the zoonotic *C. p. parvum* and anthroponotic *C. p. anthroponosum* subspecies designation (Nader et al., 2019).

Feng et al. (2017) evaluated the SNVs accumulation in several genomes of *C. parvum* IIa and IId families, which preferentially infect calves and lambs, respectively, in some European countries. This study revealed that most of the SNVs occur in subtelomeric regions of the chromosomes, with a high percentage located in coding regions of the genome, and near the half being non-synonymous. Additionally, the subtypes evaluated shared more than 50% of SNVs, and phylogenetic analysis of the SNVs data showed a robust separation of IIa sequences and IId sequences, and a high divergence with reference Iowa genome (Feng et al., 2017). These findings agree with the results obtained in this study because SNVs show a concordant relationship with gp60 subfamily typing.

Conversely, Gilchrist et al. (2018) studied the genetic diversity of thirty-two genomes of different *C. hominis* subtypes isolated from children with poor living conditions from Bangladesh. They found 36,780 SNVs that varied between the *C. hominis* isolates, with a homogeneous distribution throughout the genome and only 4% occurring with a frequency greater than 20%. These authors also built a phylogenetic tree based on the SNVs (1,582) found in those genomes, in which no groupings regarding the subtype family was observed, concluding that the use of a single marker (gp60) does not reflect the evolutionary changes of the entire genome and, in turn, confirming the weakness of the typing of unique markers for taxonomic assignments within this genus. Our findings reinforce this argument since an analysis with a more significant number of positions of different isolates considerably improves the resolution power compared to that obtained from unilocus analysis or multiple concatenated loci or partial fragments of the genome. Another aspect that could influence the topology of the phylogenomic tree obtained by Gilchrist et al. is the high rate of recombination on chromosome 6 reported among circulating isolates from endemic countries for *C. hominis* (*Li et al., 2013*; *Zahedi et al., 2013*). This feature is associated with greater genetic variability and the generation of hypertransmittable subtypes and favors a wide distribution of gp60-based allelic families in the phylogenetic tree without a cluster aggregation. The recombination phenomenon was not a relevant variable in our study since genomes analyzed correspond to isolates circulating in different geographic locations of four continents.

Several authors have proposed that phenotypic differences between *Cryptosporidium* species are related to polymorphisms on protein-coding regions (*Xu et al., 2004*; *Pain, Crossman & Parkhill, 2005*; *Bouzid et al., 2013*; *Nader et al., 2019*). In our study, the single nucleotide variants located in CDSs were analyzed and characterized as synonymous and non-synonymous changes. Compared to the *C. parvum* reference, *Cryptosporidium* species that showed the highest number of SNVs in protein-coding regions were *C. meleagridis* and *C. hominis* than 400,000 and 150,000 variants, respectively. Forty-two percent of them corresponded to non-synonymous changes. Our results on the number of SNVs in *C. hominis* differs from the data reported previously, and similarly, the same occurs with SNVs in coding regions. *Isaza et al. (2015)* identified 36,753 SNVs located on coding regions in the genome of four isolates of *C. hominis* (version 8 of CryptoDB), using as a reference the genome of *C. parvum* Iowa II. As we mentioned before, these discrepancies may be related to the methodological approach used in every study.

In *C. parvum*, the number of variants in coding regions was below 20,000 SNVs, with intraspecies differences related to a heterogeneous behavior between zoonotic and anthroponotic isolates. Additionally, it was identified that more than 50% of the SNVs located in coding regions correspond to non-synonymous mutations. In a previous study carried out by *Widmer et al. (2012)*, non-synonymous SNVs were present in a range from 28% to 32% of all SNVs, and 60% of all nucleotide positions in the two genomes were not synonymous.

Analysis of the deleterious mutations in the *Cryptosporidium* species evaluated in the study showed that 183 genes were predicted with mutations that were present in at least one genome of each species: 377 exclusive to *C. meleagridis*, 103 to *C. hominis,* and 33 to *C. parvum*. Unfortunately, 53,5% of the genes with deleterious changes were located in uncharacterized coding regions (hypothetical proteins), so the biological impact of these mutations could not be determined. Annotation of the shared and species-exclusive genes with deleterious mutations establish that most encode enzymes and proteins involved in DNA repair, recombination processes, proteins associated with the chromosomes, as well as the biogenesis of transfer RNA and ribosomes. Comparative analyzes carried out previously have found that the genes with the highest number of SNVs in *C. hominis* and

C. parvum were related to ribosome assembly, translation processes, and coding genes for proteins with transmembrane domains (Widmer et al., 2012; Isaza et al., 2015). Sikora et al. (2017b) carried out an intraspecies comparative analysis of 14 genomes of *C. hominis*. They found 18 genes with non-synonymous mutations, with only the gene that codes for a protein of the oocyst wall COWP9 (oocyst of cgd6_210) with a deleterious mutation, which was present in eight of the fourteen genomes. Mutated genes annotated in our study also code for surface proteins with transmembrane domains and proteins secreted by non-classical pathways, suggesting that the interaction processes between the parasite and the host cells could be affected. This finding agrees with that reported by other authors who have described that the processes that are mainly affected are adhesion and invasion (Li et al., 2013; Isaza et al., 2015; Gilchrist et al., 2018; Widmer, 2018; Xu et al., 2019). It has been determined that the proteins secreted by non-classical pathways usually are growth factors, inflammatory cytokines, components of the extracellular matrix that regulate cell differentiation, proliferation, and apoptosis, as well as surface proteins in parasites involved in the initial interaction with the host (Nickel, 2003). This reinforces the need to improve the annotation of *Cryptosporidium* genomes, allowing the understanding of unknown aspects related to evolution, virulence, and pathogenicity in this genus.

Indels events in the genomes of the 23 *Cryptosporidium* isolates were also evaluated in our study. More than 60% of these variants were located in CDSs, a finding that could be expected since the *Cryptosporidium* genome has a percentage of coding regions more significant than 70% (Nader et al., 2019; Xu et al., 2019). The highest number of deletions, using reference *C. parvum* IOWA, occurred in *C. meleagridis* genomes, followed by *C. hominis*, suggesting a partial loss of genome fragments these species. Indel events were less abundant than SNVs in the 23 genomes analyzed, contrary to the reports in other apicomplexan such as *Plasmodium falciparum*, in which they have been described as the dominant mechanism of polymorphism within the genome (Miles et al., 2016). Feng et al. (2017) identified 1,200 insertion events and 1,500 deletions in a comparative genomic study of *C. parvum* isolates. In our study, which analyzed a more extensive number of genomes, we found less than 100 structural variations in each of the zoonotic and anthroponotic isolates. Previous studies have determined that indels are significantly more frequent in the peri-telomeric and subtelomeric regions of *Cryptosporidium* genomes (Nader et al., 2019). Guo et al. (2015) analyzed five genomes of *C. hominis* against the reference *C. parvum* Iowa, and they identified several insertions and deletions near the telomeres on chromosome 6, associated with recombination events, which could indicate that the duplication or deletion of subtelomeric genes is involved in the differences in host specificity between *Cryptosporidium* species. These recombination events can also explain the low support obtained in the phylogeny for the *C. hominis* 30976 isolate. Members of multicopy gene families and under a strong positive selection, such as MEDLE proteins, insulin-like proteases, and mucin-type glycoproteins, related to the parasite-host interaction, are ubicated in these regions (Fan, Feng & Xiao, 2019; Feng & Xiao, 2019; Xu et al., 2019).

Although several studies have described deletions in genes encoding the MEDLE proteins in *C. parvum* and *C. hominis* (Widmer et al., 2012; Liu et al., 2016), in the present study, no structural variants were found in these genes or those encoding insulin-like proteases.

However, deletions were found in all genomes of *C. meleagridis* and at least two isolates of *C. hominis* and *C. parvum* in a gene coding for a cryptosporidial mucin (ortholog of cgd7_4020), also known as gp900. This is a microneme secreted surface glycoprotein encoded by a single copy gene; it is involved in the apical portion of sporozoites and merozoites to enterocytes, which is required to initiate the invasion process (*Okhuysen & Chappell, 2002*; *Carruthers & Tomley, 2008*). However, since there is a repertoire of adhesion proteins in *Cryptosporidium*, including the proteins related to thrombospondin, p23, the gp40 / p30 protein complex, and the Circumsporozoite-like protein—CSL (*Langer-Curry & Riggs, 1999*; *Bouzid et al., 2013*), the alterations identified in the gp900 gene probably do not affect the interaction processes between the invasive stages of the parasite and the host cell. Additional analyzes are required to determine the biological implications of these deletions in the binding and invasion process, mainly in isolates of *C. meleagridis*.

Another interesting finding in this study was identifying deletions in all genomes of *C. meleagridis* and *C. hominis* for genes that encode for proteins with a WD-40 (cgd6_4290 ortholog) and SNF2/DEXDc/HELICc domains (cdg7_420 ortholog). WD-40 domain has tryptophan-aspartic acid (WD) repeats of approximately 40 amino acids and is considered one of the ten most abundant protein domains in eukaryotes (*Xu & Min, 2011*; *Jain & Pandey, 2018*). The proteins that contain these repeats are involved in various cellular processes, acting as an adaptor in many different protein complexes or protein-DNA complexes, signal transduction, transcription, cell cycle regulation, and apoptosis; however, no enzymatic activity has been assigned (*Stirnimann et al., 2010*; *Xu & Min, 2011*). These domains have been reported as highly polymorphic in other apicomplexan protozoa, such as *Plasmodium falciparum*, suggesting the participation of WD-40 in basic cellular and metabolic processes (*Chahar et al., 2015*). SWI2/SNF2 (Switching defective -SWI and Sucrose nonfermenting-SNF) protein family are ATP-dependent chromatin remodeling factors that modulate the access of transcription factors to regulatory regions of genes (*Sullivan et al., 2013*). Previous reports indicate homologs of these domains in different apicomplexan, including *Plasmodium falciparum* (*Ji & Arnot, 1997*) and *Toxoplasma gondii* (*Sullivan et al., 2003*). *Cryptosporidium* parvum has 14 chromatin-remodeling SNF2/SWI2 ATPases (*Templeton et al., 2004*). Alterations in the genes encoding these proteins could affect the epigenetic regulatory mechanisms in this genus.

Exclusive insertions were identified in 50% of the *C. parvum* isolates in the cgd3_190 gene. This gene encodes a microneme secreted protein with epidermal growth factor - EGF domains like, which are involved in cell signaling (*Carruthers & Tomley, 2008*). In other apicomplexans, such as *Toxoplasma gondii*, these domains have been associated with adhesion processes to the host cell (*Huynh, Boulanger & Carruthers, 2014*). It has also been shown that in the presence of calcium, the EGF domains adopt an extended structure resistant to proteases, favoring the interaction of the N-terminal portion of the molecule with the host cell ligands, favoring invasion (*Carruthers & Tomley, 2008*).

CONCLUSIONS

Here we present, to our knowledge, the most comprehensive phylogenomic and genomic comparative analysis performed in the most relevant human infecting *Cryptosporidium* species, which includes complete genomes from different isolates, allelic families, and subtypes. Comparative analysis of more than 800,000 single nucleotide variable positions detected in 24 genomes of the three main species infecting humans (*C. parvum, C. hominis,* and *C. meleagridis*) generate a more robust analysis on the phylogenetic relationships between the *Cryptosporidium* species of human public health concern. This phylogenomic analysis also confirmed the *gp60* loci segregation pattern observed in subtype families. Most of the SNVs and indels detected in the study genomes were ubicated in coding regions. Genes with deleterious changes and indels were identified and annotated, whenever possible, in the three species. These mutated genes were associated with the processing of genetic information and enzymatic and metabolic processes; however, most of them remain uncharacterized and encode hypothetical proteins.

ADDITIONAL INFORMATION AND DECLARATIONS

Funding

This work was funded by the COLCIENCIAS Convocatoria 777-2017 Para Proyectos de Ciencia, Tecnología e Innovación en Salud 2017, project name: "Estudio de prevalencia, diversidad genética y genoḿica de Cryptosporidium en población VIH positiva de Antioquia" code 115-777 57608, and Vicerrectoría de Investigación (CODI), Universidad de Antioquia, grant "Finalización del genoma de referencia de C. hominis aislado UdeA01", code 2017-16-171. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Genetics and Genomics of Chronic Obstructive Pulmonary Disease

Edwin K. Silverman[1,2], **Avrum Spira**[3], **and Peter D. Paré**[4]

[1]Channing Laboratory, and [2]Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts; [3]Division of Pulmonary and Critical Care Medicine, Translational Bioinformatics Program, Clinical and Translational Science Institute, Boston University, Boston, Massachusetts; and [4]James Hogg iCAPTURE Centre for Cardiovascular and Pulmonary Research and the Department of Medicine, St. Paul's Hospital, University of British Columbia, Vancouver, British Columbia, Canada

Chronic obstructive pulmonary disease (COPD) fulfills criteria for a complex genetic disease in which environmental factors interact with multiple polymorphic genes to influence susceptibility. Finding the genes that influence susceptibility can be approached in hypothesis testing or unbiased study designs. In candidate gene association studies, genetic variation in, and/or levels of, expression of genes known or suspected to be involved in the pathogenesis of COPD are compared in affected and unaffected individuals. Although this approach is useful it is limited by our present knowledge of disease pathophysiology. Genomewide studies of gene expression and of genetic variation are now possible and are not constrained by our limited knowledge. Although both of these unbiased approaches are in their infancy, they have already provided exciting new avenues for future investigation and potentially now approaches to risk prediction and therapy.

Keywords: chronic obstructive pulmonary disease; genetics; genomics

At this symposium, three talks were given related to the genetics and genomics of chronic obstructive pulmonary disease (COPD). Peter Paré concentrated on candidate gene studies in which biologically plausible genes have been tested for variants that may impart increased risk for a rapid decline of lung function among smokers. Edwin Silverman focused on the promising approach offered by genome-wide association (GWA) studies, and Avrum Spira reviewed the state of the art with respect to the examination of gene expression at the mRNA level and its relationship to COPD phenotype.

CANDIDATE GENE STUDIES

In candidate gene association studies, genetic variants in genes thought to be involved in pathobiological pathways leading to COPD are tested for statistical association with one or more COPD phenotype. Sandford and his colleagues have taken advantage of the well-characterized Lung Health Study cohort study to examine gene variants associated with rapid decline in lung function (1). They selected the phenotypic extremes from among the approximately 6,000 individuals in that study; the approximately 300 continued smokers who had the most rapid and the approximately 300 who had the least rapid decline in FEV_1 over the first 5 years of the study. To date they have examined over 50 genes, and Table 1 shows a summary of those in which they have found polymorphisms that impart increased or decreased risk for rapid decline. Also shown is the frequency of the risk or protective allele and the odds ratio associated with that allele. Finally, the attributable risk for the specific alleles associated with increased risk is shown. The attributable risk estimates the contribution of that polymorphism to the overall risk of being in the fast or slow decline group in this "population." The association of a number of these genes with rate of decline of lung function has been replicated in independent populations (2–7).

Although such candidate gene studies are useful, they are limited by their very nature to the study of genes that are known to have some function that could contribute to the development of, or protection from, COPD. It is highly likely that many genes with unknown function contribute to pathogenesis, but until recently it has not been practical to interrogate the entire genome either at the DNA or RNA level. Recent advances in genome-wide genotyping and transcriptomic analysis make such an unbiased approach possible.

GENOME-WIDE ASSOCIATION STUDIES

Technical improvements in SNP genotyping within the past 5 years have led to markedly increased genotyping capacity at reduced cost. Combined with the identification of millions of common SNPs through the HapMap project, high-throughput genotyping approaches have made GWA studies a feasible study design in complex disease genetics. Rather than beginning with family-based linkage studies or candidate gene studies to limit the genomic regions of interest, GWA studies include a panel of hundreds of thousands of SNPs across the entire genome (8). Although there are approximately 10 million common SNPs in the human genome, approximately 500,000 well-selected SNPs can adequately capture the information of most SNPs in white and Asian populations (9). Because hundreds of thousands of statistical tests of genetic association are performed, stringent thresholds to establish statistical significance are required in GWA studies. Nonetheless, GWA studies have unequivocally identified genome-wide significant associations in a rapidly growing number of complex diseases, including age-related macular degeneration, diabetes mellitus, Crohn's disease, and asthma (10).

In a recent collaborative GWA study led by Drs. Sreekumar Pillai and David Goldstein (11), 823 subjects with COPD and 810 smoking control subjects from Norway underwent genome-wide SNP genotyping with the Illumina HumanHap550 SNP panel. Association analysis for COPD affection status was performed using logistic regression analysis with covariates including age, sex, current smoking status, and pack-years of smoking. After GWA analysis was performed, the top 100 SNPs were genotyped in 1,891 individuals from 606 pedigrees in the International COPD Genetics Network (ICGN). Family-based association analysis for COPD was performed using the same covariates as in the Norway population, and seven SNPs with significant *P* values in both populations were tested for further replication in 389 subjects with COPD from the National Emphysema Treatment Trial (NETT) and 472 smoking control subjects from the Normative Aging Study

TABLE 1. SIGNIFICANT GENETIC ASSOCIATIONS WITH RAPID DECLINE IN LUNG FUNCTION IN THE LUNG HEALTH STUDY

Candidate Gene	Odds Ratio	Relative Frequencies	Attributable Risk (%)
a1-AT Z	2.8 (1.2, 7.3)	6% vs. 3%	5
mEH Tyr113 > His, Arg139 > His *	2.4 (1.1–5.4)	7% vs. 3%	4
β2AR Glu27 > Gln	0.6 (0.4–0.8)	44% vs. 57%	
Haplotype IL1RN A1/IL1B –511T	1.4 (1–(2.1)	14% vs. 10%	4
Haplotype IL1RN A2/IL1B –511C	1.5 (1.1–2.1)	20% vs. 14%	7
IL1RN	1.6 (1.1–2.3)	72% vs. 62%	3
IL8 A-251T	1.32	58% vs. 51%	5
IL6	1.9 (1.1–3.2)	24% vs. 14%	11
MMP-1 -1607+G	1.6 (1.1–2.4)	28% vs. 19%	10
IL4RA	2.2	7% vs. 4%	5
Glutathione Transferases* (GSTP1 Ile105 > Val, GSTT1& GSTM1)	2.8 (1.1–7.2)	5% vs. 2%	3
Heme oxygenase-1	1.6 (1.0–2.3)	25% vs. 18%	10
Catalase	1.5 (1.1–2.2)	30% vs. 22%	10
Nicotine Receptor (CHRNA5)	3.0 (1.2–7.6)	41% vs. 36%	4

The candidate genes are: a1-ATZ = heterozygosity for the Z allele of alpha one antitrypsin; mEH = microsomal epoxide hydrolase; β2AR = the beta 2 adrenergic receptor; IL1RN A = the interleukin 1 receptor antagonist; IL8 = interleukin 8; IL6 = interleukin 6; MMP-1 = the matrix metalloproteinase 1; IL4R = the interleukin 4 receptor; glutathione transferases (GSTP1, GSTT1 and GSTM1); heme oxygenase-1; catalase; and the nicotine receptor (CHRNA5).

Other investigators have studied the same or additional genes in different cohorts of smokers for whom longitudinal lung function data are available. These studies confirmed the contributions of variants in microsomal epoxide hydrolase, heme oxygenase-1, and the glutathione S-transferases and have also implicated ADAM 33, cytochrome P450, and glutamate cystein ligase (2–7).

* For microsomal epoxide hydrolase and the glutathione transferases the odds ratios, frequencies, and attributable risk pertain to the presence of a compound genotype consisting of the presence of 2 (mEH) or 3 (glutathiones) risk alleles.

(NAS). Combined *P* values from all three study populations were calculated. A SNP on chromosome 15 (rs8034191) was identified with genome-wide significant association to COPD ($P = 2 \times 10^{-10}$), with the same direction of association (i.e., the same risk allele) in all three populations. There are multiple genes of interest near the most highly associated SNP, including several subunits of the nicotinic acetylcholine receptor (CHRNA3 and CHRNA5) and an iron-binding protein (IREB2). Because of the extensive linkage disequilibrium in this region, it is not possible to identify one key candidate gene; intensive study of all of the genes from this region will be required to identify all common variants and to determine if rare variants also contribute to COPD susceptibility. Of interest, this locus was also recently associated with lung cancer susceptibility in three independent reports (12–14), with peripheral vascular disease, and with nicotine addiction (15) (Table 2), suggesting that this locus may be associated with both COPD and lung cancer by influencing smoking behavior. A study from New Zealand has demonstrated associations of this genomic region with both COPD and lung cancer (16), raising the possibility that the lung cancer associations could be confounded by the frequent co-occurrence of COPD and lung cancer.

The second GWA study of a COPD-related phenotype was performed in 7,691 participants in the Framingham Heart Study (17). FEV_1/FVC was the primary phenotype analyzed. Four SNPs on chromosome 4q were strongly associated with FEV_1/FVC in Framingham, and one of these SNPs was also associated with FEV_1/FVC in the Family Heart Study. Of interest, SNPs in this same region also showed evidence for association with COPD in the Norway case-control study, ICGN, and NETT-NAS studies (11). Although FEV_1/FVC was the primary phenotype analyzed in the Framingham Heart Study and Family Heart Study, significant evidence for association to COPD affection status was also observed in the Family Heart Study. The most strongly associated SNP is near the gene that codes for the hedgehog interacting protein (HHIP), but the functional variant or variants in this region have not been identified. Significant associations to the CHRNA3/5 region were not observed in the Framingham population.

Although GWA studies in COPD are in their infancy, the chromosome 4 and 15 genetic associations are the most statistically compelling associations reported to date. Additional GWA studies of COPD and COPD-related pheno-

TABLE 2. GENOME-WIDE ASSOCIATION STUDIES WITH SIGNIFICANT ASSOCIATIONS IN THE CHROMOSOME 15 CHRNA3/5 REGION

Reference	Phenotype	Study Population	SNP with Most Significant Association	Evidence for Association
Pillai (2009) (11)	COPD	Norway: 823 cases and 810 controls	rs8034191	$P = 0.0001$

Definition of abbreviations: COPD = chronic obstructive pulmonary disease; ICGN = International COPD Genetics Network; NETT-NAS = National Emphysema Treatment Trial–Normative Aging Study; SNP = single nucleotide polymorphism.

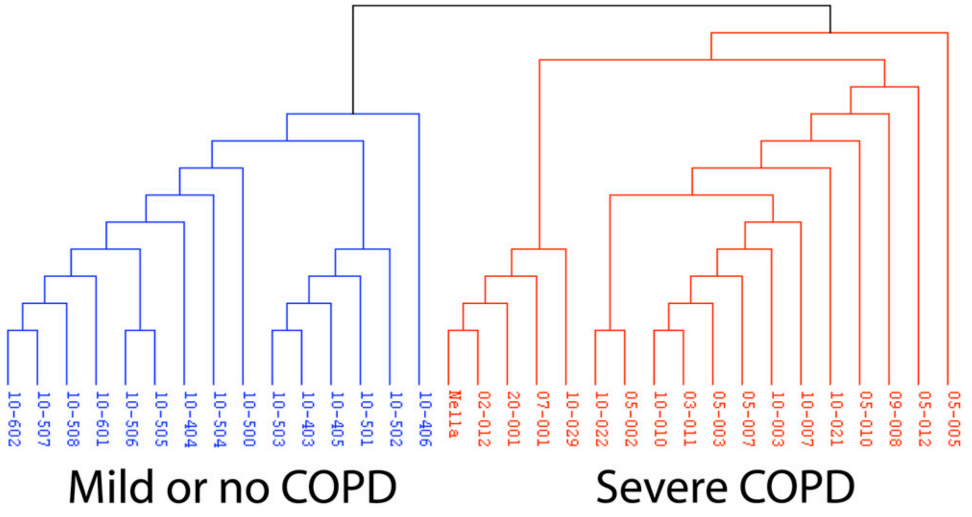

Figure 1. Hierarchical clustering of the lung tissue samples from the Spira and coworkers (18) study according to the expression of an 84 probeset biomarker derived from the study of Bhattacharya and colleagues (22). Dendogram of the samples from the study by Spira and coworkers is shown. The biomarker genes derived from the Bhattacharya study are able to accurately distinguish severe chronic obstructive pulmonary disease versus normal lung tissue in that independent cohort. Reproduced by permission from Reference 22.

types may provide novel insights into COPD pathophysiology.

GENE EXPRESSION STUDIES

Whole-genome gene expression studies of diseased lung and airway tissue provide an opportunity to gain an unbiased portrait of the COPD molecular landscape, offering insights into the processes that contribute to disease pathogenesis. While this rich molecular understanding of COPD could ultimately enable development of novel therapeutic approaches to target these pathogenic processes, we remain at the beginning of this journey. There are presently very few whole-genome expression studies of COPD lung tissue in humans (18–22). Some of the initial enthusiasm for using genome-wide gene expression in the setting of COPD has been diminished by the apparent lack of overlap, among these early studies, for genes differentially expressed in COPD lung tissue (21).

Two recent studies have shed some much-needed light on the potential relationships between existing gene expression studies of COPD lung tissue. They have attempted to overcome the inherent challenges in integrating results from relatively small studies that differ in inclusion/exclusion criteria, expression platform, and approaches for data analysis. Zeskind and coworkers (23) found that there was a high degree of overlap in the biological themes represented by the genes identified in the individual studies. While the differentially expressed genes are largely nonoverlapping, this study was able to use Gene Set Enrichment Analysis (GSEA) (24) to demonstrate that the gene-expression results from each paper share fundamental similarities. In a recently published study, Bhattacharya and colleagues (22) identified 220 genes whose expression in lung tissue was associated with COPD-related phenotypes in a cohort of 56 subjects with and without COPD. Importantly, they showed that a subset of these transcripts could serve as a biomarker distinguishing lung tissue from smokers with severe COPD versus mild or no COPD in a previously published gene-expression dataset (18) (Figure 1).

One exciting development has been the study of airway epithelial gene expression profiles in smokers with and without COPD. This work has been motivated by the concept that smoking creates a "field of molecular injury" in epithelial cells lining the entire respiratory tract, and that airway epithelial gene expression reflects host response to, and damage from, cigarette smoke (25–27). Heterogeneity in this expression pattern has been associated with tobacco-associated lung cancer (28, 29) and may provide insights into COPD-related processes. Pierrou and coworkers (30, 13) identified 200 oxidative stress-related genes that were differentially expressed in the bronchial airways between smokers with and without COPD. More recently, Tilley and colleagues (31) demonstrated that several Notch ligands, receptors, and downstream effector genes are down-regulated in the small airways (10th–12th generation) of smokers with COPD. Interestingly, Pierrou and coworkers found that a sizable fraction of the genes with COPD-specific patterns of differential expression in the airway were also differentially expressed in a previously published COPD lung tissue dataset (18). The ability to identify COPD-related processes in airway gene expression raises the possibility of developing airway biomarkers that could be used clinically to identify smokers at higher risk for developing disease as well as to serve as intermediate biomarkers of efficacy for novel and existing COPD therapies.

While there have been relatively few whole-genome expression studies of lung tissue and airways in COPD, some common themes are emerging across datasets to offer insights into disease pathogenesis. Larger studies on well-characterized cohorts of smokers with and without COPD using newer generations of microarrays and sequencing technology are needed to overcome many of the limitations of these early studies. Integration of these transcriptomic studies with whole-genome microRNA, methylation, and genotyping studies will ultimately yield a comprehensive molecular atlas of COPD.

Only a small fraction of individuals exposed to *Mycobacterium tuberculosis* develop clinical tuberculosis (TB). Over the past century, epidemiological studies have shown that human genetic factors contribute significantly to this interindividual variability, and molecular progress has been made over the past decade for at least two of the three key TB-related phenotypes: (i) a major locus controlling resistance to infection with *M. tuberculosis* has been identified, and (ii) proof of principle that severe TB of childhood can result from single-gene inborn errors of interferon-γ immunity has been provided; genetic association studies with pulmonary TB in adulthood have met with more limited success. Future genetic studies of these three phenotypes could consider subgroups of subjects defined on the basis of individual (e.g. age at TB onset) or environmental (e.g. pathogen strain) factors. Progress may also be facilitated by further methodological advances in human genetics. Identification of the human genetic variants controlling the various stages and forms of TB is critical for understanding TB pathogenesis. These findings should have major implications for TB control, in the definition of improved prevention strategies, the optimization of vaccines and clinical trials and the development of novel treatments aiming to restore deficient immune responses.

1. Introduction

Tuberculosis (TB) remains a major public health problem, as *Mycobacterium tuberculosis* infects an estimated one-third of the world's population, resulting in approximately 8.6 million new cases of TB and approximately 1.3 million deaths in 2012 [1]. TB bacilli are transmitted by the inhalation of aerosolized droplets generated by the coughing of a patient with active TB. A substantial proportion of subjects do not become infected despite sustained high levels of exposure, as shown by negative tuberculin skin test (TST) and/or interferon (IFN)-γ release assays (IGRAs), and hence never develop disease (figure 1). About 5% of infected individuals develop clinical TB within 2 years of infection, either without latency or after a very short latent phase (figure 1) [2,3]. This 'primary' TB is particularly common in children, running an acute course and often associated with extrapulmonary disease owing to dissemination of the bacillus in the bloodstream [4,5]. However, most people infected with *M. tuberculosis* develop latent TB infection (LTBI). LTBI is characterized by positive TST and/or IGRA and an absence of overt clinical signs (figure 1) [2,6,7]. Most subjects with LTBI (approx. 90–95%) never develop clinical disease. The remaining 5–10% develop clinical TB later in life, typically owing to reactivation of the

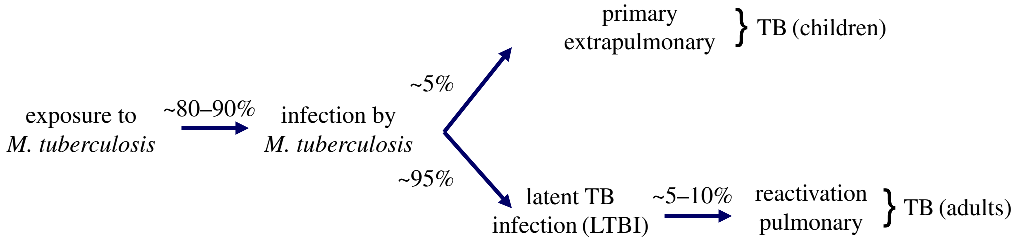

Figure 1. A schematic of the natural history of human infection by *M. tuberculosis*, and the subsequent development of clinical TB. Despite sustained high-level exposure, a substantial proportion of subjects (approx. 10–20%) do not become infected, and hence never develop disease. About 5% of infected individuals develop clinical TB within 2 years of infection; this 'primary' TB is particularly common in children, and could be associated with extrapulmonary disease. The remaining persons infected with *M. tuberculosis* develop latent TB infection (LTBI). Only a minority of subjects with LTBI (approx. 5–10%) develop clinical TB during their lifetime, typically owing to reactivation of the original infection. (Online version in colour.)

original infection. This 'reactivation' TB is predominantly a chronic pulmonary disease of adults, resulting in extensive lung damage and the efficient airborne transmission of bacteria. Hence, individuals susceptible to infection display three clinical presentations: (i) not entering LTBI (primary TB), (ii) remaining with LTBI (silent infection) or (iii) exiting from LTBI (reactivation TB).

Clinical and epidemiological surveys conducted since the 1910s have provided strong evidence that each step underlying infection or disease is controlled by host genetic factors [8–10]. Familial aggregation studies have provided the most convincing evidence [9,10]. In families with an index sputum-positive TB patient, spouses with family histories of TB were found to develop manifest TB more frequently than those without such histories [10]. Twin studies have also shown much higher concordance rates for monozygotic than for dizygotic pairs for clinical TB (combining primary and reactivation TB) [10,11]. In the seminal study conducted by Kallmann and Reisner in New York State, 308 twin pairs in which one of the pair was a confirmed index TB case were studied [11]. In this sample, the percentage of twin siblings of index cases developing manifest TB (defined on the basis of clinical, chest X-ray and sputum examinations) was 66.7% for monozygotic twins (52/78) and 23% (53/230) for dizygotic twins [11]. Interestingly, similar percentages were obtained when the sample was subdivided into groups on the basis of the known history of exposure of the twin siblings to a known active TB patient (table 1). It has long been known that the incidence of TB is particularly high in newly exposed populations [9], such as African populations and native Americans [12]. Similarly, the susceptibility to *M. tuberculosis* infection of an exposed individual, as measured by the TST, has been shown to be correlated with the region of ancestry of the individual concerned [13,14]. As for clinical TB disease, familial studies, including twin studies, have shown TB infection phenotypes (mostly TST result, considered as a quantitative trait) to be highly heritable (more than 50%, as detailed in §2).

Furthermore, a long series of experimental studies in various animal models, beginning in the 1930s, has also established the importance of host genetic background for determining the outcome of infection with *M. tuberculosis* (reviewed in [7,15,16]). In mice, a key antimycobacterial locus (the *Bcg* locus) has been shown to be allelic to *Nramp1* [17]. Knockout mice showed that CD4 T cells were required for immunity to *M. tuberculosis* and that the three most important antimycobacterial molecules required for *M. tuberculosis* destruction by phagocytes were tumour necrosis factor (TNFI-α), IFN-γ and nitric oxide synthase 2 [7,15,18,19]. Human studies have confirmed most of these findings through demonstrations of an increase in the risk of TB in AIDS patients [20,21], in patients on anti-TNF treatment [22], and in patients with genetic defects impairing IFN-γ immunity [8,23,24]. These studies have clearly demonstrated the critical importance of CD4-mediated immunity and of the interleukin (IL)-12/IFN-γ loop in baseline resistance to *M. tuberculosis*, but the reasons for which individuals otherwise displaying full immune competence develop TB remain largely unknown. In this context, the identification of genetic variants increasing the risk of TB constitutes a powerful approach to deciphering the mechanistic basis of TB pathogenesis. We provide here an overview of the principal human genes known to underlie the interindividual variability of susceptibility at each of the three main steps in the natural course of *M. tuberculosis* infection. We also discuss the contribution of genetic research to the development of new approaches to combat TB.

2. Genetic control of tuberculosis infection

There is no direct test for infection with *M. tuberculosis* and the phenotype of *M. tuberculosis* infection is inferred exclusively from quantitative measurements of antimycobacterial immunity. These assays cannot distinguish a possible anamnestic response to *M. tuberculosis* from persistent infection with the bacillus. The TST is the most widely used method [25]. The skin induration generated by the TST is caused by the accumulation of histiocytes and T cells around intradermal deposits of *M. tuberculosis* antigens. More recently, two *in vitro* blood assays, measuring either the secretion of IFN-γ by lymphocytes or the frequency of IFN-γ producing blood cells in response to *M. tuberculosis* antigens (IGRAs), have been developed [26]. TST and IGRAs assess different aspects of antimycobacterial immunity and are not fully concordant in predicting infection with *M. tuberculosis* [27]. Little or no reactivity in these tests in individuals exposed to *M. tuberculosis* is indicative of innate resistance to *M. tuberculosis* infection. In household studies, 30–50% of contacts with heavy short-term exposure do not become infected [28,29], revealing substantial heterogeneity in susceptibility to infection. We and others have focused on TST and IGRA results as quantitative traits and have shown heritability to be high for the results of both tests following exposure to *M. tuberculosis*. In Gambia, a study of healthy twins estimated the heritability of TST responsiveness and quantitative IGRA reactivity at 71% and 39%, respectively [30]. The heritability of quantitative TST reactivity in young healthy children exposed to an active TB case has been estimated at 92% in Chile [31]. In a South African familial

Table 1. Proportion of monozygotic and dizygotic twins of index cases with TB, as a function of the history of exposure of the co-twin to a known active TB patient, from the study by Kallmann & Reisner [11].

	monozygotic co-twins			dizygotic co-twins		
	number of TB cases	total number	% of TB cases	number of TB cases	total number	% of TB cases
history of exposure	36	52	69.2	46	175	26.3
without known exposure	16	26	61.5	7	55	12.7
total	52	78	66.7	53	230	23.0

sample from an area of hyperendemic TB disease, the heritability of quantitative IFN-γ release responses was estimated to be between 43 and 58%, depending on the nature of the stimulating antigen [32]. Likewise, the heritability of the frequency of antigen-specific IFN-γ^+CD4^+ and IFN-γ^+CD8^+ has been estimated at 53–74% [32]. A complex segregation analysis of TST reactivity in related household contacts of TB index cases in a Colombian population provided evidence for a major codominant gene accounting for approximately 65% of TST variability [33]. By contrast, a family study conducted in Uganda reported a lower estimate of heritability for IGRA responses (approx. 17%) [34]. However, as IGRA reactivity was adjusted for TST response in this study, this lower estimate of heritability may reflect genetic components common to the TST and IGRA responses. More recent data from Uganda carefully adjusted for shared environment yielded higher estimates for the heritability of IGRA response (approx. 30%) [35].

Despite the strong evidence in favour of an impact of genetic factors on the assays used for LTBI, only a small number of studies have aimed to identify the genetic variants underlying susceptibility to *M. tuberculosis* infection. TST reactivity was the phenotype studied in all these studies. Candidate gene association studies have focused on TST response as a binary trait, defined according to various thresholds (0, 5 or 10 mm). In a large study of 3622 TST-positive individuals and 244 TST-negative healthy controls in Ghana, an *IL10* promoter haplotype (−2849A/−1082A/−819C) was found to be significantly more frequent in TST-positive than in TST-negative subjects (15.3% versus 9.7%, odds ratio (OR) = 2.09 (1.2–3.5), $p = 0.012$) [36]. This haplotype was also associated with low levels of circulating IL-10, suggesting a role for IL-10 in the initial host response to *M. tuberculosis*. However, the similarity of age distribution between TST-negative and TST-positive subjects was not shown. Consistent with the findings for the sample from Ghana, the prevalence of TST negativity was found to be 1.5 times higher in individuals carrying the high-level IL-10-producing genotype GG at single nucleotide polymorphism (SNP) −1082A>G than in individuals carrying the AA and AG genotypes, in an indigenous population from Brazil [37]. Additional associations of cytokine genes with TST reactivity in the Brazilian sample have yet to be replicated.

In Uganda, a genome-wide (GW) linkage analysis reported results suggesting that persistent TST negativity (defined as a TST < 10 or 5 mm, according to age and HIV status) was linked to chromosomal regions 2q21–2q24 and 5p13–5q22 [38]. A study of TST reactivity in a sample of multiplex families from South Africa identified two major loci affecting TST-positivity *per se* (*TST1*) and the intensity of TST reactivity (*TST2*) [39]. *TST1* was identified by focusing on the phenotype of TST positivity versus TST negativity (i.e. TST = 0), and maps to chromosome 11p14 (lod score = 3.81, $p = 1.4 \times 10^{-5}$). A second phenotype studied was the size in millimetres of the skin induration in TST-tested subjects. The size of the induration, considered as a quantitative trait, was impacted by a locus on chromosome 5p15 which was termed *TST2* (lod score = 4.00, $p = 9 \times 10^{-6}$). The most parsimonious explanation for the role of these two loci is that *TST1* reflects innate resistance to infection with *M. tuberculosis* whereas *TST2* reflects T-cell-mediated antimycobacterial immune responses. Unexpectedly, it was subsequently discovered that a locus affecting the production of TNF by blood cells in response to bacillus Calmette–Guérin (BCG) and BCG plus IFN-γ, *TNF1*, is genetically indistinguishable from *TST1* [40]. This raises the exciting possibility that innate resistance to *M. tuberculosis* infection may involve a TNF-mediated effector mechanism. Such a possibility dovetails neatly with the function of TNF in macrophage activation during early stages of infection. No GW association study (GWAS) has yet been performed for *M. tuberculosis* infection.

3. Genetic control of severe primary tuberculosis

About 5% of infected individuals develop clinical TB within 2 years of infection (figure 1), either without latency or after a very short latent phase [3]. This 'primary' TB is particularly common in children, some of whom develop a haematogenous disseminated form (referred to here as 'severe primary TB') [2]. Severe primary TB was, by far, the most frequent form in children in areas of endemic disease before BCG vaccines and antimycobacterial antibiotics became available, resulting in high rates of mortality in children under the age of 2 years [9,23,41]. The risk of severe primary TB remains highly dependent on age at primary infection, decreasing from 10 to 20% for children under the age of 1 year to less than 0.5% for children over the age of 5 years [4,5]. These severe forms are mostly either miliary or affect the central nervous system (causing meningitis, in particular), and they remain life-threatening conditions [4,5]. BCG vaccination provides some protection against severe disseminated TB in childhood, but this protection is incomplete [42]. The development of antibiotics has greatly decreased childhood mortality due to TB, but more than 80 000 children still die from TB each year [43]. One of the fundamental unresolved questions in the field of childhood TB therefore concerns the nature of the predisposition to the development of severe clinical forms in only a minority of infected children. The findings obtained in the last decade have provided the first clue to the riddle, by showing that at least some cases of severe TB can be explained by single-gene inborn errors of immunity.

The first molecular evidence that childhood TB might reflect a Mendelian predisposition came from the observation of severe TB in children with classical primary immunodeficiencies (PIDs) [44]. In particular, a substantial number of children with chronic granulomatous disease (CGD) were diagnosed with severe TB in several countries [45–49]. In a recent survey investigating the occurrence of mycobacterial diseases in CGD patients, TB was found to be rather common in patients living in countries in which TB is endemic [50]. However, CGD is a rare disorder characterized by a high prevalence of multiple infectious diseases. Further progress towards an understanding of the genetics of severe TB came from the study of the syndrome of Mendelian susceptibility to mycobacterial diseases (MSMDs), which is defined by a selective vulnerability to weakly virulent mycobacterial species, such as BCG and environmental mycobacteria [51]. MSMD patients also often suffer from non-typhoidal, extra-intestinal salmonellosis. Since 1996, germline mutations in seven autosomal (*IFNGR1*, *IFNGR2*, *IL12B*, *IL12RB1*, *STAT1*, *IRF8*, *ISG15*) and two X-linked (*NEMO*, *CYBB*) genes have been discovered in MSMD patients [8,52–55]. High levels of locus and allelic heterogeneity have resulted in the definition of 17 different disorders, accounting for about half the known cases [56]. These defects are physiologically related, as they all result in an impairment of IFN-γ immunity. Several MSMD patients, particularly those with IFN-γR1 [57,58] and IL-12p40 [59] deficiencies, have been shown to suffer from infections due to both weakly virulent mycobacteria and *M. tuberculosis*, raising the question as to whether the TB observed in these patients could also be attributed to a monogenic predisposition.

The first answer to this question came when several siblings of MSMD patients carrying the same genetic defect as the index case were found to display severe TB as their sole infectious phenotype. This situation was initially observed in a child with partial IFN-γR1 deficiency, who was a sibling of an MSMD patient [60], and was subsequently observed in a male subject from a large multiplex X-linked kindred carrying a specific mutation of *CYBB* impairing the IFN-γ-dependent respiratory burst in macrophages [53]. However, the most common genetic defect identified in patients with severe TB to date is complete IL-12Rβ1 deficiency [61]. In one family, an IL-12Rβ1-deficient sister of a patient with MSMD developed abdominal TB [62]. Several children with severe TB and complete IL-12Rβ1 deficiency in the absence of a familial history of infections with weakly virulent mycobacteria have been identified [63,64]. In a more systematic search for *IL12RB1* mutations in 50 children with severe TB, two patients (4%) with complete IL-12Rβ1 deficiency were identified [24]. Overall, these results provided proof of principle for monogenic predisposition to severe TB, and raised the possibility that a substantial proportion of children with severe TB carry single-gene inborn errors of immunity. This proportion has been estimated at up to 45% by theoretical calculations [23], and can now be determined experimentally, by whole-exome and whole-genome sequencing. These findings have already paved the way for new treatments based on physiopathology. While until recently it was difficult to envision how point-of-care genotyping could be implemented in TB diagnosis, recent advances in hand-held PCR technology now suggest patient genotyping as a viable tool even in low- and middle-income countries [65,66]. The best example is provided by patients with IL-12Rβ1 deficiencies presenting TB owing to impaired IFN-γ production, for whom treatment with recombinant human IFN-γ, in addition to antimycobacterial drugs, has been shown to be effective [67].

4. Genetic control of pulmonary tuberculosis

Most people infected with *M. tuberculosis* present LTBI and do not develop primary TB (figure 1). Epidemiological studies have indicated that approximately 5–10% of individuals with LTBI go on to develop active TB during their lifetime, this risk decreasing with increasing time since infection [7,68]. Molecular epidemiology studies have shown that active TB due to reactivation of the original strain can occur decades after the initial infection [69]. The progression of infection within a subject from LTBI to pulmonary TB (PTB) reflects an impairment of host resistance to *M. tuberculosis*. This process may be triggered by acquired immunodeficiency, such as HIV infection or anti-TNF treatment. However, in subjects without overt immunodeficiency, the pathogenesis of reactivation remains unclear. As mentioned above, there is strong evidence that the development of PTB is influenced by host genetic factors. This genetic control is also likely to be different from that involved in primary TB [23,70]. Indeed, the study of genetic susceptibility to adulthood PTB has proved more difficult than that of susceptibility to severe childhood TB. In particular, no variants of genes from the IL12/IFN-γ circuit have been convincingly associated with PTB as yet. Current knowledge resulting from attempts to identify the genetic variants associated with PTB points to underlying heterogeneity, possibly due, at least in part, to the long-standing, multistep relationship between *M. tuberculosis* and its human host, through the natural history of PTB disease [71,72]. In particular, it is possible that specific subgroups of individuals with PTB have certain genetic risk factors, whereas other subgroups have other genetic risk factors. Such subgroups could potentially be defined on the basis of individual factors, such as clinical characteristics, or extrinsic factors, such as pathogen variability.

The vast majority of studies conducted to date to determine the molecular basis of PTB susceptibility have been association studies investigating the role of specific candidate genes. Most classical genetic association studies investigating PTB have focused on candidate genes, and a number of common risk variants have been reported in particular in immunity-related genes such as those encoding DC-SIGN, Toll-like receptors 1 and 2, vitamin D receptor, TNF, IL-1β or some HLA class II molecules [73]. However, there has been a lack of consistency between most of the reported results of independent studies [73,74]. One of the most convincing findings was the identification of associated polymorphisms of the *NRAMP1* gene (alias *SLC11A1*), the human orthologue of the murine *Nramp1* gene [17]. Following the initial association reported in a Gambian population [75], a meta-analysis of a large number of studies showed that several *NRAMP1* polymorphisms were significantly associated with PTB in African and Asian populations, but not in populations of European descent [76]. Two studies also provided evidence of a role for *NRAMP1* in early-onset TB. The first showed significant linkage to the *NRAMP1* gene in a large aboriginal Canadian family in which an outbreak of TB occurred [77]. In a follow-up study, common polymorphic alleles of *NRAMP1* were shown to be strong risk factors for TB (OR = 3.13 (1.54–6.25)) in children living in Texas, mostly of Hispanic and African origin, resulting in an allelic association acting in the opposite direction to that observed in adults [78]. These observations are consistent with the hypothesis that *NRAMP1* polymorphisms affect the speed of progression from infection to TB disease, accounting for the high frequency of some common alleles in patients with pediatric disease and the paucity of patients with the same alleles among TB cases with disease onset during adulthood. Overall, these studies provide strong support for a role of *NRAMP1* in TB, with an effect that is heterogeneous across populations, epidemiological settings and clinical phenotypes. They also highlight the importance of considering age at TB onset in these analyses. Generally, in the field of infectious diseases, stronger genetic effects are more pronounced in early-onset cases than in late-onset cases [70]. For example, in leprosy the association of genetic variants with disease has been shown repeatedly to be highly age-dependent [79,80].

The concept of stronger genetic effects associated with early-onset disease was further supported by the positional cloning of the first major locus conferring predisposition to PTB, which was found to be linked to chromosome region 8q [81]. Refined association mapping of the linked region identified variants of the *TOX* gene as strongly associated (OR = 3.09(1.99–4.78)) with the development of early-onset PTB (before 25 years of age) in populations from Morocco and Madagascar [82]. *TOX* encodes a nuclear factor involved in the development of T cells [83], particularly the CD4$^+$ T cells [84,85] critical for immunity to mycobacteria [20]. Conversely, GWASs on PTB, considered as a single phenotype, have met with limited success to date. A first GWAS performed on a large sample from Gambia and Ghana identified a single SNP with a weak effect (OR = 1.19 (1.12–1.26)) located in a ‘gene desert’ on chromosome 18 as a risk factor for PTB [86]. Further imputation of the original Ghanaian data identified a second locus on chromosome 11p13 as protective against TB [87]. The main protective SNP allele was well replicated in the Gambian sample but displayed only borderline associations in Indonesian patients and in a very large sample (more than 10 000 subjects) of subjects from Russia [87]. Another GWAS recently conducted in a South African population confirmed the protective effect of the chromosome 11p13 factor but identified no new risk loci of GW significance [88]. Finally, a GWAS in Asian populations identified an independent TB risk locus in chromosome region 20q12, only in patients defined as ‘young cases’ (OR = 1.73 (1.42–2.11)) [89]. Based on the observed age distribution of this latter study, young cases were defined as having an onset of TB before the age of 45 years, although more refined analyses with lower age thresholds showed that higher deviations of p-values from the null hypothesis were observed with younger age cut-offs despite the lower number of cases in each subset [89]. Overall, a striking feature of these GWASs is the lack of replication of the PTB susceptibility factors previously detected in candidate gene analyses [8,73,74]. Overall, the GWAS results suggest that common variants may have a limited impact on predisposition to adult PTB, at least when considered as a single phenotype, and point to underlying heterogeneity, possibly in phenotype definition.

5. Perspectives

TB was long considered to be purely infectious, but there is increasing evidence to suggest that this disease also reflects host genetic vulnerability. However, the precise nature of the genetic factors involved remains largely unknown. Several non-mutually exclusive explanations can account for the difficulties experienced in identifying the causal variants, especially in GWASs. Genetic heterogeneity may play a role, together with a complex mode of inheritance involving incomplete penetrance and modifier genes [90,91]. Likewise, the contribution of rare variants to TB pathogenesis is attracting attention for two main reasons: (i) conceptually, rare variants bridge the gap between Mendelian and complex inheritance, and may account for the major loci identified through linkage studies [56,70,92]; (ii) experimentally, these variants abound in the genome and can now be studied by whole-exome and whole-genome sequencing [93,94]. However, the phenotypic heterogeneity of TB-related traits causes more serious problems. For example, three measurements of immune reactivity are currently used to detect infection with *M. tuberculosis*. However, the results of these tests display limited concordance, and each assay captures a different aspect of the antimycobacterial response [27]. MSMD probably provides the best example of the critical interplay between phenotype and genetic control. The syndromic phenotype is MSMD, but the identification of the underlying genetic defects was greatly facilitated by establishing endophenotypes (e.g. specific patterns of cytokine production such as IL-12 and IFN-γ [95]), guiding subsequent genetic analysis. Endophenotypes are more closely related to gene function and are likely to be generally useful for the dissection of TB phenotypes. In PTB, the most commonly used phenotype-defining characteristic is the presence of *M. tuberculosis* in the sputum of patients, regardless of the other clinical, microbiological and demographic covariables. This approach completely ignores the dynamic nature of pulmonary TB, the likelihood of different stages of this process being under different genetic controls, as shown in a mouse model of BCG infection [96], and the possible impact of the *M. tuberculosis* strain on LTBI and clinical outcome [97–99]. The need for improvements in the definition of a more homogeneous and more refined TB phenotype for genetic studies is also demonstrated by the strong impact of age at onset of disease on our ability to detect genetic effects in clinical TB [78,82].

Traditional genetic approaches will also benefit from a better understanding of the molecular mechanisms of TB pathogenesis throughout the infectious cycle. For example, transcriptomic studies, including the search for loci involved in the expression of genes and/or microRNAs (expression quantitative trait loci, eQTL) in cell- or tissue-specific studies [100], based on RNA-seq in particular [101], are of major importance. A transcriptomic analysis of peripheral blood cells identified a neutrophil-driven IFN-α/β-inducible transcript signature in individuals with active PTB [102]. This blood signature was validated in independent studies [103–105], and was shown to be different from that of several infectious and pulmonary diseases [102,106], providing new insights into the most relevant pathways and candidate biomarkers for investigation in TB [107]. Some eQTLs associated with variation in gene expression levels in dendritic cells infected with *M. tuberculosis* [108] have also provided interesting candidate loci that remain to be tested for association with TB infection phenotypes. It is also possible that somatic mutations and epigenetic effects have a substantial impact on clinical susceptibility to TB, particularly in patients with late-onset disease [70]. Epigenetic mechanisms play a critical role in the immune system [109], and their investigation, particularly through GW analyses of the methylome [110,111], should provide new insight into the genetic basis of infection and clinical TB [112]. These epigenetic factors may be influenced by environmental and/or other host factors, such as diet, vitamin status or ageing [113,114], leading to additional possible gene × environment interaction effects. One of the main challenges in the next few years will be the integrated analysis of all these different sources of genomic information [115,116]. Finally, studies of various animal models, including zebrafish [90,91], rodents [15,16,117] and non-human primates [117,118], will be essential to provide critical information complementary to that obtained in human studies [7].

In the principal countries in which TB is endemic, disease control is based largely on passive case identification and drug treatment. This approach has proved effective for decreasing case mortality and human suffering, but the impact of current TB control on global TB trends is less clear [119–121]. The emergence and spread of extremely drug resistant strains resistant to the antibiotics currently available are warning signs that additional approaches will be required to halt endemic TB [122]. The availability of an effective vaccine against post-primary TB would provide us with a useful tool for decreasing TB transmission. Unfortunately, recent vaccine trials have yielded disappointing results [123,124], possibly reflecting our incomplete understanding of intrinsic vulnerability to TB as (i) mice that are genetically more resistant to *M. tuberculosis* infection benefit more from BCG vaccination than their susceptible counterparts [125], (ii) antimycobacterial immunity in humans is highly heritable and, thus, has a strong genetic component [30–32] and (iii) TB patients are more likely to suffer subsequent episodes of TB than would be expected on the basis of population incidence, strongly suggesting that TB patients have a susceptibility that cannot be overcome by conventional vaccination and/or antibiotics [126]. The strong positive selection of T-cell epitopes by *M. tuberculosis* across clinical strains presents an additional hurdle for vaccine development [127]. Taken together, these experimental data and observations *in natura* suggest that any effective TB vaccine must take into account the genetic susceptibility of patients if it is to trigger a protective response. Likewise, new therapeutic approaches based on the complementation of a specific immunodeficiency identified by human genetics should also have a positive complementary impact on the classical treatment of TB. For example, young patients developing disseminated TB during primary infection owing to the impaired production of IFN-γ (such as those with *IL12RB1* mutations) would benefit from targeted treatment with recombinant IFN-γ [67]. Finally, the recent discovery of *TST1* as a locus with an impact on intrinsic resistance to infection with *M. tuberculosis* provides another example for the usefulness of human genetics in TB control [39]. Once identified, the molecular mechanisms underlying *TST1* might constitute attractive targets for the prevention of infection by drug-based or vaccine interventions. The prevention of infection is the gold standard for stopping the TB endemic and studies of host genetics are an important weapon in the war against TB.

An integrated map of HIV genome-wide variation from a population perspective

Guangdi Li[1,2*], Supinya Piampongsant[2], Nuno Rodrigues Faria[3], Arnout Voet[4], Andrea-Clemencia Pineda-Peña[2,5], Ricardo Khouri[2,6], Philippe Lemey[2], Anne-Mieke Vandamme[2,7] and Kristof Theys[2*]

Abstract

Background: The HIV pandemic is characterized by extensive genetic variability, which has challenged the development of HIV drugs and vaccines. Although HIV genomes have been classified into different types, groups, subtypes and recombinants, a comprehensive study that maps HIV genome-wide diversity at the population level is still lacking to date. This study aims to characterize HIV genomic diversity in large-scale sequence populations, and to identify driving factors that shape HIV genome diversity.

Results: A total of 2996 full-length genomic sequences from 1705 patients infected with 16 major HIV groups, subtypes and circulating recombinant forms (CRFs) were analyzed along with structural, immunological and peptide inhibitor information. Average nucleotide diversity of HIV genomes was almost 50% between HIV-1 and HIV-2 types, 37.5% between HIV-1 groups, 14.7% between HIV-1 subtypes, 8.2% within individual HIV-1 subtypes and less than 1% within single patients. Along the HIV genome, diversity patterns and compositions of nucleotides and amino acids were highly similar across different groups, subtypes and CRFs. Current HIV-derived peptide inhibitors were predominantly derived from conserved, solvent accessible and intrinsically ordered structures in the HIV-1 subtype B genome. We identified these conserved regions in Capsid, Nucleocapsid, Protease, Integrase, Reverse transcriptase, Vpr and the GP41 N terminus as potential drug targets. In the analysis of factors that impact HIV-1 genomic diversity, we focused on protein multimerization, immunological constraints and HIV-human protein interactions. We found that amino acid diversity in monomeric proteins was higher than in multimeric proteins, and diversified positions were preferably located within human CD4 T cell and antibody epitopes. Moreover, intrinsic disorder regions in HIV-1 proteins coincided with high levels of amino acid diversity, facilitating a large number of interactions between HIV-1 and human proteins.

Conclusions: This first large-scale analysis provided a detailed mapping of HIV genomic diversity and highlighted drug-target regions conserved across different groups, subtypes and CRFs. Our findings suggest that, in addition to the impact of protein multimerization and immune selective pressure on HIV-1 diversity, HIV-human protein interactions are facilitated by high variability within intrinsically disordered structures.

Keywords: HIV genome, Genomic diversity, Conservation, Peptide inhibitor, HIV-human protein interaction, HIV phylogenetic tree, HIV inter- and inter-clade genetic diversity, Selective pressure, Protein multimerization, Protein intrinsic disorder

Background

As the causative agent of AIDS, the Human Immunodeficiency Virus (HIV) represents a worldwide threat to public health and the economy. The HIV pandemic is characterized by extensive genomic diversity caused by multiple factors including multiple zoonotic transmissions into human populations, high rates of viral evolution and recombination [1]. HIV has two major types, HIV-1 and HIV-2, which are further divided into groups, subtypes and recombinant forms. Globally, over 90% of HIV infections belong to HIV-1 group M viruses, which have been classified into 9 subtypes (A-D, F-H, J, K) and more than 50 circulating recombinant forms (CRFs) [1]. The high genetic diversity of the HIV genome has challenged the development of drugs and vaccines [2].

The HIV genome contains nine genes that encode fifteen viral proteins (Additional file 1: Figure S1). Three major genes, *gag*, *pol* and *env*, code for structural proteins (Matrix, Capsid, Nucleocapsid, p6), enzymes (Protease, Reverse transcriptase (RT), Integrase) and envelope proteins (GP120, GP41), respectively. The remaining genes code for regulatory (Tat, Rev) and accessory proteins (Vif, Vpr, Vpu/Vpx, Nef) [3]. These viral proteins can exhibit multiple functions and interact with various human proteins during the viral life cycle [4,5].

During the past three decades, many antiviral inhibitors have been designed to prevent HIV replication by targeting different viral proteins [6]. These anti-HIV peptides and small-molecule inhibitors either act by blocking active sites of viral enzymes or interrupting protein interactions [6]. For instance, the fusion inhibitor T20 (Enfuvirtide, Fuzeon), a peptide derived from the GP41 heptad repeat region, can efficiently inhibit viral entry by interrupting interactions between the GP41 helices [7]. For all existing drug classes, mutations in the HIV genome can cause drug resistance [8]. Therefore, inhibitors have been preferentially developed to target conserved regions of different viral proteins [9]. HIV genetic diversity also challenges the development of a global HIV vaccine [10]. While the vaccine trial STEP was unable to show preventive vaccination in subtype B infected cohorts [11], the Thai trial RV144 showed for the first time that prime-boost vaccination provided a modest efficacy in patients infected with CRF01_AE [12]. For vaccine and drug design, it remains important to investigate the genomic diversity of different HIV groups, subtypes and CRFs at a population level.

Despite a large body of knowledge on different aspects of HIV pathogenesis, a large-scale analysis that reveals the genome-wide diversity within and between different HIV groups, subtypes and CRFs is still lacking. Although previous HIV genomic studies have reported subtype distribution, genetic variability, disease progression, evolutionary rate, positive selective pressure and the origin of HIV [11-27], most studies reported their findings using either reference genomes or small cohorts of less than 100 patients or sequences in a single subtype. HIV-1 subtype B which dominates infections in developed countries is the most studied subtype, largely due to historical reasons [28]. For instance, the adaptive evolution during acute infection was evaluated only in 11 individuals infected with HIV-1 subtype B [14]. In light of using HIV consensus sequences as vaccine candidates, an analysis on the genetic difference between consensus sequences and circulating strains was limited to subtypes B and C using less than 100 sequences [2], while other subtypes also prevail worldwide [29].

The last three decades have seen an accumulation of HIV data including full-length genomic sequences, protein crystal structures, HIV-human protein interactions, human T-cell epitope information and antiretroviral peptide inhibitors derived from the HIV genome. By integrating distinct but complementary sources of large-scale HIV datasets, this study aims to characterize HIV genome-wide diversity and to determine multiple factors that shape HIV genomic diversity.

Results

Genome-wide diversity within and across HIV types, major groups and subtypes

We quantified the nucleotide and amino acid diversity of the HIV genome using 2996 full-length sequences sampled from 1705 patients (Table 1). The amino acid diversity was 53.8% (95% confidence interval (CI): 53.0-54.6%) between HIV-1 and HIV-2, 41.1% (CI: 25.6-54.3%) between HIV-1 groups, 18.0% (CI: 15.6-19.6%) between HIV-1 subtypes, 12.0% (CI: 8.6-14.4%) within HIV-1 subtypes and 1.1% (CI: 0.3-2.2%) within HIV-1 patients (Figure 1A). Similarly, nucleotide genomic diversity was found to be the highest when comparing

Figure 1 (See legend on next page.)

(See figure on previous page.)

Figure 1 Distribution of HIV genome-wide diversity and phylogenetic tree. (A) Distribution plots of amino acid diversity in the HIV genome. The plots show the genomic diversity within HIV-1 infected patients (HIV-1 intra-patient, blue), within HIV-1 subtypes (HIV-1 intra-subtype, green), between HIV-1 subtypes (HIV-1 inter-subtype, red), between HIV-1 group M and group N (HIV-1 inter-group, yellow), between HIV-1 group M and group O/P (HIV-1 inter-group, black) and between HIV-1 and HIV-2 (pink). Distribution plots of nucleotide genomic diversity are shown in Additional file 1: Figure S2. **(B)** Maximum likelihood phylogenetic tree of HIV groups and pure subtypes. Green cones indicate HIV-1 subtypes in group M, while orange cones denote other HIV groups. All phylogenetic branches have bootstrap supports of more than 85% except one containing subtypes J, H and C. Branch lengths from the root to HIV-1 and HIV-2 are shortened for visualization purposes. SIV strains were not included in our phylogenetic tree. Visualization software: FigTree V1.4.0 (http://tree.bio.ed.ac.uk/software/figtree/). **(C)** Distribution plots of amino acid diversity in 6 major HIV-1 subtypes and CRFs (B, A1, C, D, CRF01_AE, CRF02_AG). X- and y-axes indicate the amino acid diversity and the proportions of sequence pairs, respectively. Six subplots in the first and second rows show the intra-subtype amino acid diversity of 6 HIV-1 subtypes and CRFs. Three subplots in the third row show the distribution of inter-subtype genomic diversity (B vs A1, B vs C, B vs 01_AE). One genomic sequence per patient (Table 1) was used for our analysis. Distribution plots of the other inter-clade genomic diversity are shown in Additional file 1: Figure S3. **(D)** Average inter- and intra-clade genomic diversity of HIV-1 and HIV-2. The top right matrix demonstrates results for amino acid diversity, the bottom left matrix for nucleotide diversity. HIV subtypes and groups are shown on the left side of the matrix.

HIV-1 and HIV-2 (mean: 48.32%, CI: 47.8-48.9%), followed by HIV-1 inter-group (37.5%, CI: 26.0-45.7%), HIV-1 inter-subtype (14.7%, CI: 12.2-15.8%), HIV-1 intra-subtype (8.2%, CI: 5.3-10.0%) and HIV-1 intra-patient diversity (0.6%, CI: 0.2-1.4%) (Additional file 1: Figure S2). As expected, the trend in HIV genomic diversity corresponds with the phylogenetic relationships between groups and pure subtypes in HIV-1 and HIV-2 (Figure 1B).

We next quantified genomic diversity within and between individual HIV clades (Figure 1C, Additional file 1: Figure S3). Within each HIV clade, amino acid diversity was consistently higher than nucleotide diversity (Figure 1D). CRF01_AE showed the lowest genomic diversity (nucleotide: 5.7%, amino acid: 8.7%) among the 10 HIV-1 subtypes with at least 10 sequences available (Figure 1D). Sequence variability was not uniformly distributed along the full-length HIV genome, but similar patterns were consistently observed in HIV group, subtype and CRF genomes at the nucleotide and amino acid levels (Figure 2A, B). Moreover, the estimated geographical distribution of HIV-1 genomic diversity (Additional file 1: Figure S4) showed a good agreement with the reported geographical distribution of HIV-1 subtypes [29].

Among all HIV proteins, Integrase was the most conserved protein (mean ± deviation: 4.5 ± 1.1%), while GP120 varied the most (21.3 ± 2.5%) (Table 2). Pairwise comparisons of genetic diversity between subtype B and the other clades identified conserved regions in the Capsid, Nucleocapsid, Protease, RT, Integrase, Vpr and the N terminus of GP41 (Figure 2C). Despite the different degrees of sequence diversity along the full-length genome, the nucleotide and amino acid compositions were comparable across the 16 group and subtype genomes (Figure 3A, 3B).

Multiple factors shape HIV-1 genomic diversity

We next evaluated three potential factors (protein multimerization, immunological constraints, HIV-human protein interactions) that shaped the HIV genomic diversity. Firstly, we calculated the average diversity at amino acid positions of the 15 HIV-1 proteins (Figure 3C). For every HIV-1 group, subtype and CRF, the average amino acid diversity was significantly higher in the monomeric proteins (Nucleocapsid, Vpr, Vpu, p6) than in the multimeric proteins (Matrix, Capsid, Protease, RT, Integrase, Vif, Tat, Rev, GP120, GP41, Nef) ($p\text{-value} < 0.05$) (Additional file 2: Table S1). This suggests that protein multimerization imposes a constraint on the HIV-1 amino acid variability. Besides our diversity analysis, we also measured synonymous (dS) and non-synonymous (dN) substitution rates in the HIV-1 subtype A1, B, C and CRF01_AE genomes, which contained more than 100 sequences in our genomic datasets (Additional file 2: Table S2). Mann-Whitney U tests were used to compare the distribution of dN, dS and the ratio of non-synonymous to synonymous substitutions (dN/dS) between the monomeric and multimeric protein groups. We found that the distributions of dN/dS and dN in these two groups were significantly different ($p\text{-value} < 0.05$) in HIV-1 subtypes A1, B, C and CRF01_AE (Additional file 2: Table S3). This suggests that multimeric proteins are under the stronger negative selective pressure than monomeric proteins.

Secondly, we evaluated the amino acid variation in the known CD4 T cell, CD8 T cell and antibody epitopes (see Materials). By measuring the diversity of 3066 amino acid positions, we identified 919 (30%) variable positions with amino acid diversity above 12.9% (the average amino acid diversity within subtype B) using 657 subtype B genomic sequences. Univariate analysis showed that these variable positions were preferably located within antibody epitopes (OR 1.43, CI: 1.15-1.79, Fisher's exact test, $p\text{-value} = 0.0015$) and CD4 T cell epitopes (OR 1.73, CI: 1.18-2.96, $p\text{-value} = 0.0438$), but not within CD8 T cell epitopes (OR 1.11, CI: 0.82-1.51, $p\text{-value} = 0.498$) (Figure 2A).

Thirdly, we mapped 1352 interactions between 1052 human and 15 HIV-1 proteins using the HIV-human protein interaction dataset (Figure 3D, see Materials). The following three observations support the hypothesis

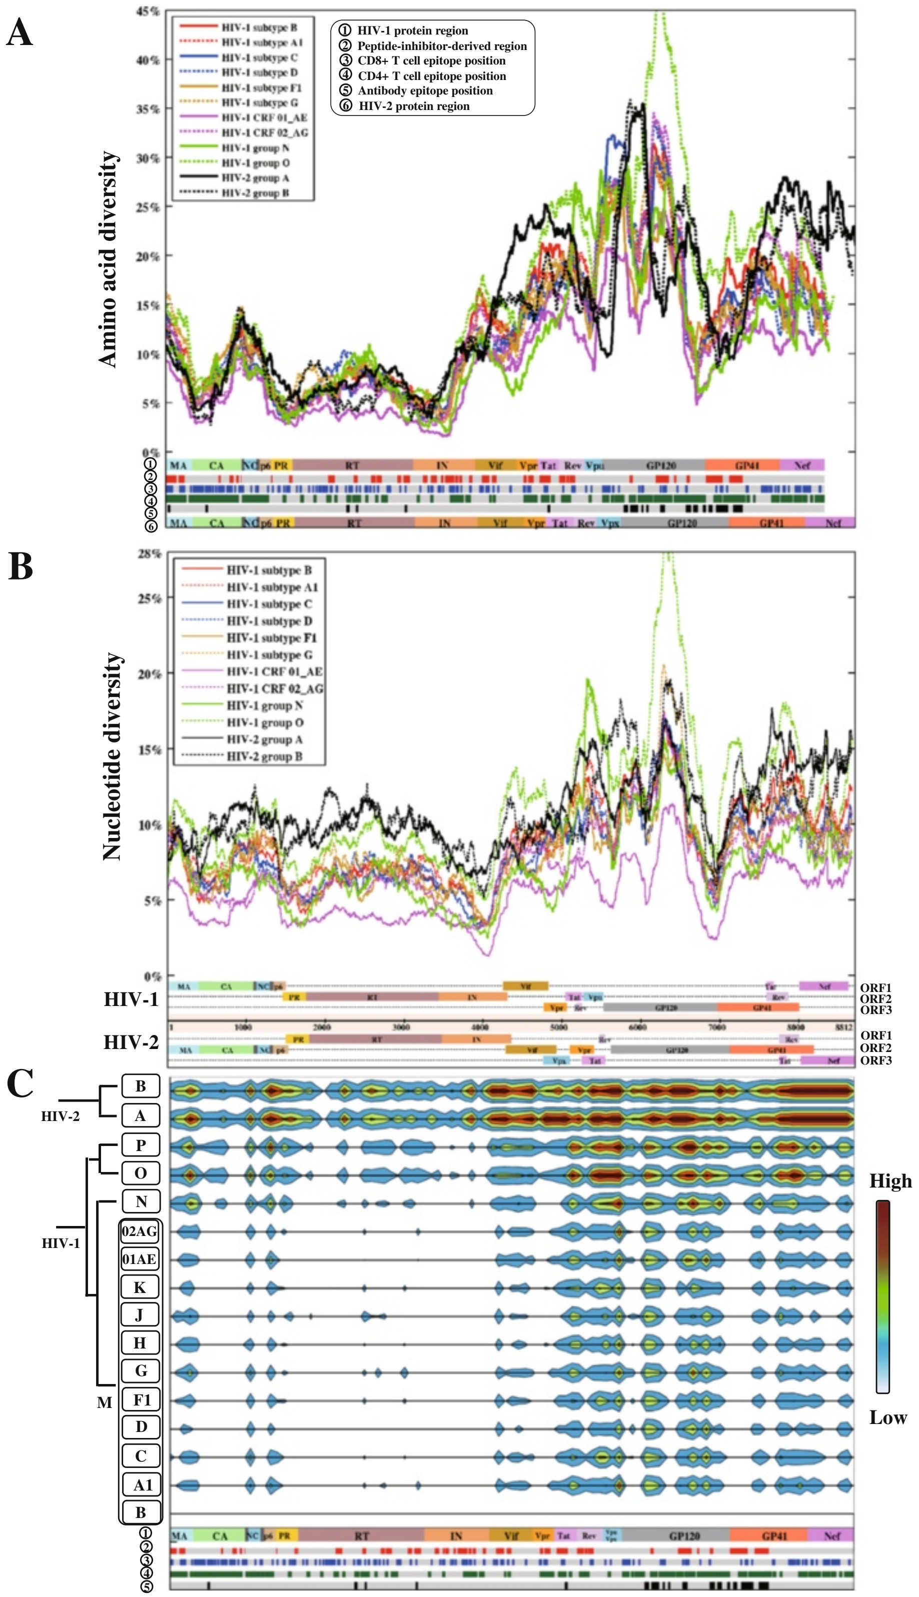

Figure 2 (See legend on next page.)

(See figure on previous page.)

Figure 2 Plots of amino acid and nucleotide diversity in the HIV full-length genome. (A) Amino acid diversity along the HIV full-length genome using the sliding windows (window size: 100AA; also see the plots of exact diversity values in Additional file 1: Figure S5). Each colored plot shows the density of amino acid diversity for one HIV group, subtype or CRF genome, indicated by the figure legend. Six layers are shown beneath the plots: (1) HIV-1 protein regions (HXB2 reference) are concatenated and shown with abbreviated names (e.g. MA: matrix); (2) peptide-inhibitor-derived region; (3) CD8+ T cell epitope position; (4) CD4+ T cell epitope position; (5) antibody epitope position; (6) HIV-2 protein region (BEN reference). **(B)** Nucleotide diversity along the full-length HIV genome using sliding windows (window size: 300 nucleotides; also see the plots of exact diversity values in Additional file 1: Figure S6). Each colored plot shows the density of nucleotide diversity for one HIV group, subtype or CRF genome, indicated by the figure legend. Annotated HIV-1 and HIV-2 reference genomes are shown beneath; each track contains one open reading frame (ORF). Long terminal regions in the HIV genome are not shown. **(C)** Contour map of inter-clade amino acid diversity between HIV-1 subtype B and the other HIV genomes. Inter-clade amino acid diversity was calculated by a sliding window of 30 amino acids over the HIV genome (low: ≤1 AA difference, high: ≥25 AA differences). Five colored layers beneath the contour map are annotated similarly in **(A)**.

that the amino acid diversity of HIV-1 proteins is associated with HIV-human protein interactions. (1) Univariate analysis showed that HIV-1 proteins with higher amino acid diversity interact with more human proteins (Pearson's coefficient = 0.74, p-value = 0.0017). Polynomial regression analysis further identified a second-order model that fitted the correlation between these two variables (Figure 4A, adjusted R-squared: 0.82). (2) Intrinsically disordered structures in HIV-1 proteins can interact with multiple interaction partners [30]. Univariate analysis showed a significant correlation between the average amino acid diversity and the average disorder scores of HIV-1 proteins (Pearson's coefficient = 0.64, p-value = 0.015, Figure 4B). (3) The levels of HIV-human protein interactions clustered according to the functional roles of the HIV-1 proteins, which have different functional roles and requirements for interactions with human proteins (Figure 4C). HIV regulatory proteins (Tat, Rev) and envelope proteins (GP120, GP41) had the largest number of interactions with different human proteins (568 for the regulatory proteins, 322 for the envelope proteins), while viral enzymes had the least number of interactions (Figure 4C). The average amino acid diversity of envelope proteins (20.4%) and regulatory proteins (18.8%) was higher than that of accessory proteins (16.0%), structural proteins (9.0%) and viral enzymes (5.9%) (Additional file 1: Figure S7). Our findings suggest that HIV-1 proteins with higher genetic diversities have larger intrinsically disordered structures and interact with more human proteins.

Peptide inhibitors are mainly derived from conserved subtype B genomic regions

We investigated the 121 HIV-derived peptide inhibitors reported between 1993 and 2013 (Additional file 2: Table S4). Figure 5A illustrates the GP41 structure and the GP41-derived region of T20 as an example of HIV-derived peptide inhibitors. Peptide inhibitors had on average a length of 25 AAs (range: 3 to 73), a charge of +0.27 at pH 7.2 and a molecular weight of 2953 g/mol. Most common amino acids in these peptide inhibitors were leucine, glutamic acid and isoleucine (Additional file 1: Figure S8). Comparisons

Figure 3 Nucleotide and amino acid composition of HIV genomes and 3D mapping of HIV-human protein interactions. (A) Nucleotide composition for HIV-1 and HIV-2. X-axis represents the HIV groups, subtypes and CRFs. Y-axis shows the average proportions of nucleotides (A, T, C, G) using the HIV genomic sequence datasets (one sequence per patient, Table 1). **(B)** Amino acid composition for HIV-1 and HIV-2. X-axis represents HIV groups, subtypes and CRFs. Y-axis shows the average proportions of amino acids using the HIV protein sequence datasets (one sequence per patient, Table 1). **(C)** Distribution plots of amino acid genetic diversity for 15 HIV-1 subtype B proteins. Each subplot demonstrates a viral protein. X- and y-axes indicate the amino acid diversity and the proportions of amino acid diversity, respectively. Red lines inside the distribution plots indicate the mean values of amino acid diversity at individual proteins. **(D)** Top and side views of 3D HIV-human protein interaction networks. HIV-1 proteins with protein names annotated are indicated by green spheres. Human proteins that interact with only one HIV-1 protein are indicated by blue spheres in the outer circle (one human protein one sphere). Human proteins that interact with more than one HIV-1 protein are indicated by purple spheres above the plane of HIV-1 proteins. The height of the layers above the plane indicates the number of HIV proteins that a human protein interacts with. Below, human proteins are clustered if they interact with a set of more than one HIV-1 protein. Abbreviation names have been described in the abbreviation list. Visualization software: Geomi V2.0(http://sydney.edu.au/engineering/it/~visual/geomi2/).

between the 121 peptide sequences and the consensus sequences of 16 HIV group, subtype and CRF genomes showed the highest sequence similarity with subtype B (79.8%) (Figure 5B). Aspartic acid to asparagine (25.7%) was the most common amino acid substitution between the consensus subtype B sequence and the peptide inhibitor sequences (Figure 5C).

We characterized peptide-derived regions in the subtype B genome. Of the 894 amino acid positions from which the 121 peptide inhibitors were derived, 41.2% were located in helix structures and 60.2% displayed less than 5% genetic diversity in the subtype B genome. Forty-two inhibitors had IC_{50} or EC_{50} values less than 1 μM and were derived from 249 amino acid positions in the HIV-1 genome (Additional file 2: Table S4). In the subtype B genome, these 249 positions displayed significantly lower amino acid diversity compared to the genome-wide diversity (Figure 5D, 10.1% vs 12.9%, p-value = 0.019), and were likely to be from conserved (amino acid diversity < 5%, OR: 1.43 (1.09-1.88), p-value = 0.016), solvent exposed (OR: 2.47 (1.88-3.24), p-value = 3.9E-11) and intrinsically ordered structures (disorder score < 0.4, OR: 1.75 (1.21-2.51), p-value = 0.0019) (Figure 5E).

Integrated findings from our analyses on HIV-1 genomic diversity, HIV-derived peptide inhibitors and protein structures are visualized in Figure 6. The HIV genomic sequence datasets and our toolbox developed for data visualization, genomic diversity analysis and HIV genomic alignments are freely available in Additional file 3.

Discussion and conclusions

To our knowledge, this study provides the first large-scale analysis that investigates the genomic variability of 16 major groups, subtypes and CRFs in HIV-1 and HIV-2. While previous studies have reported the diversity of HIV genomes in small cohorts of patients (n < 250) [11-24,31], our analyses evaluated HIV genome-wide diversity using 2996 full-length genomic sequences sampled from 1705 patients worldwide. We evaluated three important aspects of HIV genomic diversity using the integrated datasets of genomic sequences, protein structures, HIV-human protein interactions, human immune epitopes and HIV-derived peptide inhibitors. Firstly, we quantified HIV genomic diversity at the individual and population levels. Secondly, we reported possible associations between HIV-1 amino acid diversity and protein multimerization, immunological constraints and HIV-human protein interactions. Thirdly, we mapped conserved regions in the HIV genome and characterized experimental and clinically used HIV-derived peptide inhibitors [7].

Quantification of HIV genomic diversity

HIV-1 genomic diversity is the lowest within single patients and increases in the following order when different patients are considered: within subtypes, between subtypes, between groups and between HIV types (Figure 1). A nucleotide genomic diversity was quantified to be 48.3% between HIV-1 and HIV-2, 37.5% between HIV-1 groups, 14.7% between HIV-1 subtypes, 8.2% within HIV-1 subtypes, and 0.6% within single patients infected with HIV-1. These results are in a good agreement with previous studies which analyzed less than 100 sequences [13,23]. Our study quantified genomic diversity at the population level using the largest sequence dataset ever analyzed, thereby resulting in robust and accurate estimations.

As shown in Figure 2, the degree of HIV genetic diversity varied along the full-length genome. A comparison of the amino acid diversity of HIV proteins revealed the highest diversity in the envelope proteins, followed by the regulatory, accessory, structural and enzymatic proteins (Figure 4, Table 2). Our diversity analysis showed comparable results compared to our previous studies, which reported the amino acid diversity of Gag and Rev using 10862 and 4632 sequences respectively [9,32]. In contrast, estimated amino acid diversities for Pol (5.7 ± 0.9%) and Env (18.7 ± 2.7%) displayed higher values than

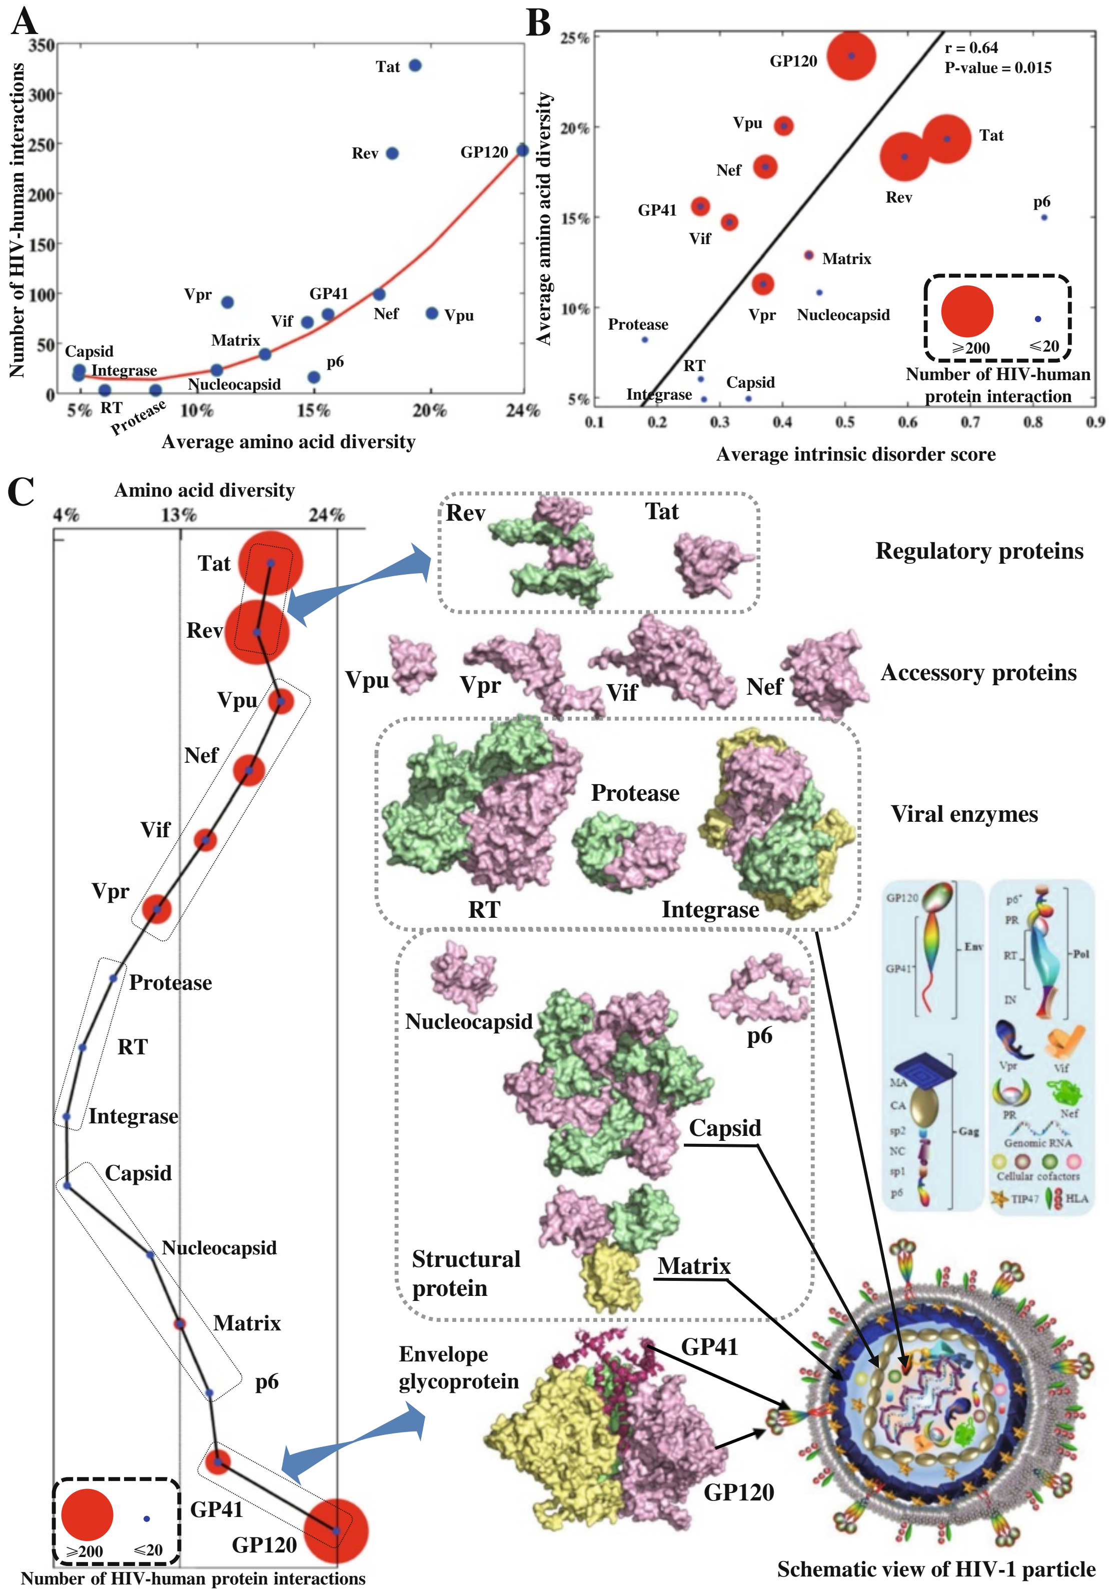

Figure 4 (See legend on next page.)

Figure 4 Correlations between HIV-1 protein diversity and HIV-human protein interactions, protein disorder and viral particle structures. **(A)** Plot of polynomial regression between the HIV-1 protein diversity (x-axis) and the number of HIV-human protein interactions (y-axis). The second-order model is $\mathcal{Y} = 8346\mathcal{X}^2 - 1223\mathcal{X} + 57.96$ (adjusted R-squared: 0.82, root-mean-square error: 42.31). **(B)** Plot of average protein disorder score and average amino acid diversity in HIV-1 proteins. Red circles indicate the number of HIV-human protein interactions at individual viral proteins, for visualization purpose, scaled between 20 and 200 interactions (proteins with fewer than 20 interactions are scaled to the same size as those with 20, proteins with more than 200 interactions are scaled to the same size as those with 200). Average amino acid diversities of HIV-1 proteins are calculated using subtype B sequences (one genomic sequence per patient, Table 1). **(C)** Clustering of HIV-1 proteins and schematic view of HIV-1 viral particle. On the left, each colored circle represents a viral protein positioned according to the clusters of protein functions. The size of each red circle indicates the number of HIV-human protein interactions involving each HIV-1 protein (see **(B)**). On the right, the schematic view of mature viral particle is visualized at the bottom with annotations indicated in the inserted figure legend. Above, surface representations show the structures of HIV-1 proteins that are grouped according to their functional roles. Different units in HIV-1 multimeric proteins are indicated with different colors and HIV-1 monomeric proteins are colored pink. HIV-1 protein structures are scaled according to their precise protein sizes for direct comparison. Visualization software: PyMOL V1.5 (http://www.pymol.org/).

previous reports analyzing fewer than 100 sequences of subtypes A and B [24]. Using large-scale sequence datasets, our study thus provides a complete estimation of the genetic diversity in 16 HIV proteins.

HIV genomic diversity is shaped by multiple factors

HIV genomic diversity is driven by the high rates of viral replication, recombination and mutation [33], but other factors also play a role in shaping HIV genomic diversity. For instance, positive selection was significantly identified in the overlapping reading frames of the HIV-1 subtype B genome, probably due to functional and structural requirements [26]. To evaluate other potential factors, we correlated HIV amino acid diversity with protein multimerization, human immunological constraints and HIV-human protein interactions. We showed that CD4 T cell and antibody epitope positions in the HIV-1 genome were likely to have high amino acid diversities, supporting the hypothesis that the human immune system imposes a diversifying selective pressure on the HIV-1 genome [26]. Moreover, we found that the average amino acid diversity was significantly lower in the multimeric than in the monomeric proteins, suggesting that protein multimerization places a constraint on HIV-1 sequence conservation. While synonymous substitution rates were not significantly different, nonsynonymous substitution rates were significantly lower in multimeric proteins (Additional file 2: Table S3), suggesting that the negative selective pressure may be stronger for multimeric proteins. Previous findings on other protein families have also shown that multimeric proteins are relatively conserved and have less tolerance for amino acid substitutions, probably because of the structural and functional constraints [34-37].

We mapped 1352 HIV-human protein interactions between 15 HIV-1 proteins and 1052 human proteins. A strong association was found between the amino acid diversity of HIV-1 proteins and the number of HIV-human protein interactions (Figure 4A). HIV-1 proteins with higher genetic diversities tended to interact with more human proteins. This is probably associated with structurally disordered regions in HIV-1 proteins (Figure 4B), which provide the structural flexibility for HIV to interact with multiple human proteins [30]. For instance, GP120 uses five hypervariable loops (Additional file 1: Figure S12) to interact with various human proteins [38]. An intricate landscape of HIV-human protein complexes is made by HIV to exploit human cellular machineries during the HIV infection and production [39]. Despite the high variability of HIV, it is surprising that the nucleotide and amino acid compositions were remarkably constant across all HIV-1 and HIV-2 clades (Figure 3A, 3B), suggesting that other constraints may be active to restrict the HIV genetic diversity [25]. For instance, HIV RNA structures require the stable nucleotide compositions for the reverse transcription [25].

Conserved drug targets in the HIV-1 genome

Many peptide inhibitors derived from HIV-1 proteins have shown promising antiviral activities and some of these inhibitors are currently under clinical trials [40,41]. Our study summarized HIV-derived peptide inhibitors published between 1993 and 2013 (Additional file 1: Figure S12-S21, Additional file 2: Table S4), and mapped the positions of these inhibitors to the HIV-1 genome (Figure 6). We showed that most peptide inhibitors were derived from the regions of HIV-1 subtype B proteins (Figure 5B), which had conserved, solvent exposed and intrinsically ordered structures (Figure 5E). This information enhances current understanding of HIV-derived peptide inhibitors, which may provide valuable guidelines for the design of novel peptide inhibitors [42,43].

In the full-length genome, we identified conserved regions in Capsid, Nucleocapsid, Protease, RT, Integrase, Vpr and N-terminal domain of GP41 (Figure 2). These conserved regions have been targeted by known anti-HIV inhibitors (Figure 6). For instance, over 40 experimental inhibitors with promising antiviral activities have been designed to target Capsid and Nucleocapsid [9]. HIV enzymes (Protease, RT, Integrase) are targeted by the majority of the FDA-approved

Figure 5 Characterization of HIV-derived peptide inhibitors. (A) Cartoon representation of GP41 structure. The red structure indicates the region from which peptide inhibitor T20 was derived (PDB: 3H01). **(B)** Bar plot of sequence similarities between peptide inhibitor sequences and the sequences of HIV-derived regions in the consensus genome of different HIV clades. X-axis presents the HIV groups, subtypes and CRFs. Y-axis shows the sequence similarity between peptide inhibitor sequences and the sequences of HIV-derived regions in the consensus genomes of HIV groups, subtypes or CRFs. **(C)** Amino acid replacements between peptide inhibitor sequences and HIV-derived regions in the subtype B genome. The percentage values (%) are colored using heat maps. **(D)** Distribution (bee-swarm) plots of amino acid diversity in the full-length subtype B genome (black crosses), peptide-derived regions (blue diamonds) and peptide-derived regions of those inhibitors whose IC_{50}/EC_{50} are less than 1 μM (red circles). Each shape represents the amino acid diversity at one protein position. Two-sample Kolmogorov-Smirnov tests were performed to compare diversity distributions (significance level: 0.05). **(E)** Plot of amino acid diversity (x-axis), disorder score (y-axis) and solvent accessible surface area of peptide-inhibitor-derived regions (contour map, darker red indicates larger accessible surface areas). GP41 inhibitor T20 is also annotated. For individual peptide inhibitors, the average amino acid diversity, disorder score and solvent accessible surface areas are shown in Additional file 1: Figure S9, S10 and S11, respectively.

antiretroviral drugs. Peptide inhibitor T20 targets the N-terminal heptad domain of GP41 [44]. Overall, our sequence analysis mapped the conserved drug target regions in the HIV-1 genome, providing useful information for drug design.

Implications for HIV vaccine development

HIV subtype- and geography-specific vaccination has been proposed to contend with the challenges imposed by the high HIV genetic diversity [2]. Previous vaccine trials were carried out in regional populations dominated by a single

Figure 6 An integrated map of HIV-1 genomic diversity and protein structures. All 15 HIV-1 proteins are mapped in the circle with 8 layers, showing the schematic view of HIV-1 peptide inhibitors (layer 1), protein secondary structures (layer 2, dark blue: helix structures, light blue: beta-strand structures, white: random-coil structures), protein disorder scores (layer 3), amino acid diversity at individual positions (layer 4), human CD4/CD8/antibody epitope regions (layer 5, three sub-layers from inside to outside represent CD8+ T cell, CD4+ T cell and antibody epitope regions), HXB2 reference indices (layer 6), peptide-inhibitor-derived regions (layer 7) and the protein structures are colored according to the diversity of amino acid positions (layer 8, low: 0%, high: ≥30%). Three major genes (*gag*, *pol*, *env*) are annotated in the center. Structures of multimeric HIV-1 proteins are shown outside the circle and different protein units are colored separately. The list of PDB data is available in Additional file 2: Table S5. Visualization software: Circos V0.64 (http://circos.ca/).

HIV-1 subtype or CRF. For instance, the STEP [11] and RV144 [12] vaccine trials targeted patient populations mainly infected by subtype B and CRF01_AE, respectively. Particularly, the RV144 trial in 2009 showed the first sign that a prime–boost strategy achieved a modest vaccine efficacy (31.2%) in the heterosexual population, which was at risk for infections with CRF01_AE [12,31]. In our analysis, CRF01_AE has the lowest genomic diversity among the 12 analyzed HIV groups, subtypes and CRFs (Figures 1D, 2A, 2B). It is thus tempting to speculate that the low diversity of CRF01_AE may have contributed to the success of the RV144 trial.

As conserved epitopes are ideal targets for potential vaccines to contend with the high HIV diversity [24,45], our study highlighted position-specific conservation along the full-length HIV genome (Figure 6). Moreover, HIV-1 consensus sequences have been considered as potential vaccine candidates to minimize genetic diversity between vaccine candidates and circulating strains [2]. Previous analyses on fewer than 100 Matrix and GP160 sequences reported that genetic diversity between subtype-specific consensus sequences and circulating strains was only half of the genetic diversity between circulating strains from the same subtype [2]. We found that in the full-length HIV genome, this effect was much smaller as we only observed a 32.5% reduction of the genomic diversity (8.3% vs. 12.3%, Additional file 1: Figure S22). As the most explored vaccine target protein, GP120 has the highest genetic diversity among all HIV proteins (Table 2), presenting a challenge in the search for broadly neutralizing antibodies and vaccines [46]. Furthermore, we mapped the global distribution of HIV-1 genomic diversity (Additional file 1: Figure S4). Our results showed the highest HIV genomic diversity in Central Africa, the birthplace of HIV [1,29], which suggested the difficulty of implementing HIV vaccines in this region.

Limitations and future perspectives

The limited number of full-length genomic sequences for HIV-1 subtypes H, J and K, group P and HIV-2 group B (n < 10) may have affected our estimation of sequence diversity, but consistent patterns were detected in the full-length genome across different HIV groups and subtypes (Figure 2). Sequence diversity investigations at a population level for such clades may improve when adding more sequences from individual proteins. However, it would also result in difficulties (e.g. lack of patient or treatment information) that may affect our confidence in data quality, and consequently the accuracy of our results. Our structural analysis focuses on HIV-1 proteins because most PDB data are available for HIV-1 but not for HIV-2 (Additional file 2: Table S5). Beside the multiple factors described in our study, other driving forces may shape HIV genetic diversity [25,47] and the genetic diversity data reported in our study can be useful for further investigations. Information on positions involved in HIV-human protein interactions is largely lacking, restricting our analysis from exploring the genetic diversity of protein interaction positions. Despite an extensive search, anti-HIV peptide inhibitors other than the ones described here may have been developed, but major changes in our conclusions regarding the known peptide-derived regions are not expected. Future studies are still needed to clarify how to improve vaccines and anti-HIV inhibitors based on the information of HIV genomic diversity. The increased knowledge of genome-wide diversity from our study may contribute to a better rational design of HIV vaccines and inhibitors.

Methods

HIV genomic sequence dataset

In August 2013, we retrieved 3607 nucleotide genomic sequences of major HIV-1 and HIV-2 clades (HIV-2 group A and B, HIV-1 group N, O, P, subtype A1, B, C, D, F1, G, H, J, K, CRF01_AE, CRF02_AG) from the HIV Los Alamos database (www.hiv.lanl.gov/). HIV-1 subtype was determined by the Rega [48] and COMET [49] subtyping tools. The quality criteria for removing duplicates and sequences with hypermutations, stop codons, ambiguous nucleotides or discordant subtype classification were described in [9]. The sequence dataset that fulfilled the quality criteria comprised 2996 genomic sequences, sampled from 1684 HIV-1 and 21 HIV-2 patients between 1982 and 2013. Information on genomic sequence datasets is summarized in Table 1.

Nucleotide genomic sequences were aligned using MUSCLE [50]. Protein regions encoded by their respective open reading frames (ORFs) were concatenated according to the reference strains (HIV-1: HXB2, HIV-2: BEN). For each HIV protein coding region, the translation of nucleotide to amino acid sequence alignments was optimized by our nucleotide to amino acid alignment toolbox. This toolbox maximizes amino acid matches, including in overlapping reading frames, based on the BLOSUM62 substitution matrix. Sequence alignments were further curated using Seaview v4.3 [51]. To show the alignment quality, we measured the percentages of deletions and insertions in the multiple sequence alignments (MSAs) of HIV genomes, which were less than 1.31% in 16 individual HIV clades (Additional file 2: Table S6). Our alignment toolbox and genomic sequences are available in Additional file 3.

PDB, HIV-human protein interaction, CD4/CD8/antibody epitope datasets

As of February 2014, we queried HIV PDB data from the RCSB Protein Data Bank using sequence search; PDB quality was then examined using PDBREPORT [52] (Additional file 2: Table S5). We extracted HIV-human protein interactions (interaction type: physical interaction) from the NCBI HIV-1 human protein interaction database [53]. From the HIV Los Alamos database (http://www.hiv.lanl.gov/content/immunology/), we extracted the human CD4 T cell and antibody epitopes in HIV-1. For human CTL/CD8 T cell epitopes, we included the best-defined CTL epitopes of the A-list described in [54] (Additional file 2: Table S7).

HIV-derived peptide inhibitor dataset

HIV-derived peptide inhibitors have their amino acid sequences derived from HIV proteins. We searched for English articles in PubMed published between January 1983 and September 2013 using the keywords “HIV peptide inhibitor”, “HIV [protein name] peptide” and “HIV [protein name] inhibitor”. References from primary studies, review articles and peptide design papers were also reviewed. If more than one peptide inhibitor were reported in one publication, only the most promising peptide inhibitors as indicated by the abstract of articles were collected. If data on the same inhibitors was reported by more than one publication, only the latest results were retained. Additional file 2: Table S4 summarizes the 121 peptide inhibitors with corresponding information on peptide sequences, peptide-derived regions, target proteins, inhibitory activities and references.

Protein secondary structure

For HIV-1 proteins (Rev, GP41) whose crystalized structures are not fully resolved in the PDB data, we used the sequence-based method PSIPRED V3.0 [55] to estimate protein secondary structures. For the other HIV-1 proteins with available PDB data (Additional file 2: Table S5), we assessed protein secondary structures using both PSIPRED V3.0 [55] and 2Struc [56]. 2Struc is a software platform which integrates 8 PDB-based methods: DSSP_CONT, DSSP, KAKSI, PALSSE, P-SEA, STICKS, STRIDE and XTLSSTR [56]. Alpha-helix, beta-strand and random-coil structures were estimated using the majority voting of above 9 methods. Prediction similarities between these 9 methods are shown in Additional file 1: Figure S23.

Protein intrinsic disorder

Protein disordered regions are exploited by the virus to invade cellular host systems [30]; these regions are often structurally unstable without their partner molecules [57]. We estimated the intrinsically disordered structures of HIV-1 subtype B proteins using three software packages: MetaPrDOS [57], VSL2P [58] and PreDisorder v1.1 [59]. A disorder score (a numerical value between 0 and 1) of each amino acid position was estimated by 17 methods in these 3 software packages. An amino acid position was estimated as intrinsically disordered if its disorder score was above the cutoff value of 0.5 [57-59]. The intrinsically disordered positions were identified based on the majority voting of 17 methods. Prediction similarities between these 17 methods are shown in Additional file 1: Figure S24.

Solvent accessible surface area

We estimated protein solvent accessible surface areas (ASA) using Chimera V1.6.1 [60] (default parameters). Provided with PDB data in Additional file 2: Table S5, we calculated the ASA at each amino acid of all HIV-1 protein units. For each of the 20 amino acids, a distribution of its ASA scores over 15 HIV-1 proteins was obtained and the maximum ASA was identified therein. An amino acid at a specific position was considered buried if its ASA was lower than 25% of the maximum ASA for the corresponding amino acid [61] (Additional file 2: Table S8).

Phylogenetic analysis

Our phylogenetic analysis was performed using 1384 nucleotide genomic sequences of 14 HIV groups and pure subtypes (thus excluding CRFs), obtained from the earliest sampling time (one sequence per patient). To prepare the alignment, we also removed ambiguous regions containing multiple insertions, deletions and hypervariable positions (HXB2 index: 1126-1182, 6866-7003, 7106-7154, 7773-7842, 7981-8032, 8897-9383). Maximum-likelihood phylogenetic trees were obtained using the multi-threaded FastTree V2.1 [62]. Our software parameters were set to 100 bootstrap replicates, the fully optimized GTR (generalized time-reversible) model, the continuous gamma distribution and the exhaustive nearest-neighbor interchange approach. The consensus phylogenetic tree with bootstrap supports was obtained using the seqboot tool in Phylip V3.69 (http://evolution.genetics.washington.edu/phylip.html).

Ratio of non-synonymous and synonymous rate (dN/dS)

Following the protocol described in [26], we performed the dN/dS analysis for HIV-1 subtype B using 495 genomic sequences sampled from different treatment-naïve patients. We firstly constructed a maximum-likelihood phylogenetic tree using FastTree V2.1 [62] (parameters: continuous gamma distribution, generalized time-reversible (GTR) model). Provided with the constructed phylogenetic tree and the codon sequence dataset, we then applied HyPhy V2.1.0 [63] to estimate the non-synonymous (dN) and synonymous (dS) substitution rates. We employed the single likelihood ancestor counting (SLAC) model with the optimized GTR [63]. Ambiguous nucleotides were resolved by averaging over all possible states for the ancestral sequence reconstruction [63]. Statistical significance of dN/dS was measured by the continuous extension of binomial distributions [63]. The above procedure was also performed for HIV-1 subtype A1, C and CRF01_AE genomes using our sequence datasets (Additional file 2: Table S2).

Quantification of sequence diversity

Sequence diversity was calculated based on the pairwise nucleotide (NT) and amino acid (AA) comparisons [9,64]. When calculating the amino acid diversity of HIV genome, we concatenated the amino acid sequences of 15 HIV protein coding regions in the full-length genome. Suppose the sequence dataset D contains L sequences with N positions, genetic diversity at position n is calculated by: $GD(D_n) = 1 - \frac{2}{L(L-1)} \sum_{i=1}^{L} \sum_{j=i+1}^{L} \delta\left(D_{n,i} = D_{n,j}\right)$, where $D_{n,i}$ is the NT or AA form of the position n at the i$^{\text{th}}$ sequence in the dataset D, δ represents the Kronecker symbol, $\delta(D_{n,i} = D_{n,j})$ equals 1 if $D_{n,i}$ is identical to $D_{n,j}$; otherwise 0. Given the sequence dataset D, intra-clade genetic diversity *AGD(D)* is defined as the average genetic diversity of all positions:

$$AGD(D) = 1 - \frac{1}{N} \sum_{n=1}^{N} \frac{2}{L(L-1)} \sum_{i=1}^{L} \sum_{j=i+1}^{L} \delta\left(D_{n,i} = D_{n,j}\right).$$

Suppose two sequence datasets D1 and D2 aligned with the same reference genome have the number of sequences L_1 and L_2 respectively. The inter-clade genetic diversity between D1 and D2 is defined as:

$$RGD(D1, D2) = 1 - \frac{1}{N} \sum_{n=1}^{N} \frac{1}{L_1 \times L_2} \sum_{i=1}^{L_1} \sum_{j=1}^{L_2} \delta\left(D1_{n,i} = D2_{n,j}\right).$$

Furthermore, only positions for which less than 20% of sequences had gaps were considered and gaps were treated as missing data. Intra- and inter-clade genetic diversity was measured using one genomic sequence per patient, while intra-patient diversity was calculated using more than one genomic sequence sampled from individual patients. The Mann–Whitney *U* test was performed to compare the distributions of genetic diversity and a significant difference was identified if a p-value was lower than 0.05 [65]. Our Matlab implementation of genomic diversity analysis is available in Additional file 3.

Genome Medicine

REVIEW Open Access

Recent advances in malaria genomics and epigenomics

Sebastian Kirchner, B. Joanne Power and Andrew P. Waters*

Abstract

Malaria continues to impose a significant disease burden on low- and middle-income countries in the tropics. However, revolutionary progress over the last 3 years in nucleic acid sequencing, reverse genetics, and post-genome analyses has generated step changes in our understanding of malaria parasite (*Plasmodium* spp.) biology and its interactions with its host and vector. Driven by the availability of vast amounts of genome sequence data from *Plasmodium* species strains, relevant human populations of different ethnicities, and mosquito vectors, researchers can consider any biological component of the malarial process in isolation or in the interactive setting that is infection. In particular, considerable progress has been made in the area of population genomics, with *Plasmodium falciparum* serving as a highly relevant model. Such studies have demonstrated that genome evolution under strong selective pressure can be detected. These data, combined with reverse genetics, have enabled the identification of the region of the *P. falciparum* genome that is under selective pressure and the confirmation of the functionality of the mutations in the *kelch13* gene that accompany resistance to the major frontline antimalarial, artemisinin. Furthermore, the central role of epigenetic regulation of gene expression and antigenic variation and developmental fate in *P. falciparum* is becoming ever clearer. This review summarizes recent exciting discoveries that genome technologies have enabled in malaria research and highlights some of their applications to healthcare. The knowledge gained will help to develop surveillance approaches for the emergence or spread of drug resistance and to identify new targets for the development of antimalarial drugs and perhaps vaccines.

Background

Malaria, caused by unicellular protozoan *Plasmodium* spp. parasites, is an ancient disease and remains a major threat to human health and wellbeing. Five species of *Plasmodium* are currently recognized as causing human malaria, of which the most lethal is *P. falciparum* (Pf). In 2015, the World Health Organization estimated that the maximal annual burden imposed by malaria, whilst decreasing, still stands at 214 million (range 149–303 million) cases that result in 438,000 (range 236,000–623,000) deaths [1]. Drug resistance to frontline antimalarials continues to arise and spread, exacerbated by slow progress in the introduction of alternatives. Properly efficacious vaccines remain a hope, not a likelihood. Against this background, genome-based research on malaria seeks to provide new avenues for therapeutic or prophylactic development based upon biological insights such as the identification of new drug targets and vaccine candidates.

The landmark of the completion of the genome sequence of a laboratory strain of Pf was achieved over a decade ago [2] (Fig. 1). This has since been accompanied, thanks to plummeting costs and advances in next-generation sequencing (NGS) technologies, by the whole-genome sequencing (WGS) of a wide range of species representing all the major clades of the genus, although the genomes of all known human infectious *Plasmodium* species remain to be sequenced [3]. However, the combination of NGS and WGS has enabled the development of innovative large-scale genomic studies, for example, for genomic epidemiology [4]. Such population genomics, fueled by collaborative consortia (for example, the Malaria Genomic Epidemiology Network (MalariaGEN; http://www.malariagen.net), have allowed the dynamics of global and local population

structures to be assessed and adaptive change in parasite genomes to be monitored in response to threats, such as artemisinin (ART). This is especially true for single-nucleotide polymorphisms (SNPs), and while other aspects of genome variation (such as indels and copy number variation) might currently lag behind, the gaps in the database are known and are firmly in the sights of researchers.

The template *Plasmodium* genomes have provided the substrate for the application of an explosion of other post-genome survey technologies that have been largely exclusively applied to Pf, such as transcriptomics, proteomics, metabolomics, and lipidomics, and that map the general and stage-specific characteristics of malaria parasites. These data are warehoused in expensive but critical community web sites such as PlasmoDB (http://www.Plasmodb.org). This in turn has been exploited by ever improving forward and reverse genetic capabilities to assign function to genes, steadily reducing the >60 % of genes of unknown function that were originally catalogued [2]. Advances that will be highlighted in this review include: the unraveling of the molecular mechanisms of parasite resistance to ART; the functional identification of some of the histone-modifying enzymes that write the epigenetic code (such as Pf histone deacetylase 2 (PfHDA2)) and the proteins that read it (such as Pf heterochromatin protein 1 (PfHP1)) that, with others (such as RNaseII), play a significant role in the regulation of antigenic variation and commitment to sexual development.

Furthermore, the genomes of the host and of a growing number of mosquito vectors have been characterized in both increasing number and depth, permitting meta-analyses of these genomes in combination with *Plasmodium* infection. These studies have revealed important loci associated with resistance to the malaria parasite in the host and vector, respectively [5, 6], and indicate the genomic hotspots in the genetic arms race that malaria has stimulated.

We also review the recent advances in this very active area of malaria genomics and control of gene expression and emphasize any benefits that these advances may have for the development of therapies and interventions (Table 1).

Human genomics

The infrastructure required to effectively collect, collate, and analyze large genomes for epidemiological studies (that is, genome-wide association studies (GWAS)) is so costly that it is best achieved in consortia. These can work at such a scale that analyses are powered to a degree that GWAS findings become more certain and the global context of the effect of, for example, human genetics on susceptibility to malaria is more reliably resolved. The African Genome Variation Project recognizes the significant diversity of ethnicities and, therefore, genotypes and, through WGS, imputation, and SNP mapping, seeks to build a database through which disease incidence and outcome can be reliably associated with haplotypes [7]. Already, such wider analyses have confirmed SNP associations with five well-known traits, including hemoglobinopathies and glucose-6-phosphate dehydrogenase (G6PD) deficiency, but have refuted 22 others that had been linked by smaller-scale studies [8]. This study also showed opposing effects of G6PD on different fatal consequences of malaria infection, revealing a hitherto unsuspected complexity of associations. Ongoing analyses have revealed new, although unsurprising, examples of haplotypes of loci associated with protection from severe malaria, such as the glycophorin locus on human chromosome 4 [8, 9].

Vector genomics

In Africa, malaria is mainly transmitted by female *Anopheles gambiae* (Ag) mosquitoes. Approaches to understanding the role of Ag mosquito genomics in malaria transmission have been similar to those of the African Genome Variation Project. Thus, the Ag1000G project (https://www.malariagen.net/projects/ag1000g) involves 35 working groups that have sampled Ag mosquitos from 13 malaria endemic countries and that aim to establish the levels of Ag genome diversity, establish population structures, and link these to the ecology of disease transmission. The *Anopheles* vector genome is very dynamic. Comparative vector genomics has revealed rapid gene gain and loss compared with *Drosophila* and significant intragenus diversity and mixing in genes involved in both insecticide resistance and antimalarial immunity [10, 11]. The nature and extent of such diversity precludes the application of classic GWAS approaches and a novel approach of phenotype-driven, pooled sequencing coupled with linkage mapping in carefully selected founder colonies has been used to map vector phenotypes. This study recently revealed *TOLL11* as a gene that protects African mosquitoes against Pf infection [6].

Parasite genomics

Full genome sequences are now available for many strains of Pf [2], *Plasmodium vivax* [12], and *Plasmodium knowlesi* [13] among the human infectious parasites. Primate and rodent infectious species that are frequently used as model parasites have also been sequenced and include *Plasmodium berghei* (Pb), *Plasmodium cynomolgi, Plasmodium chabaudi* and *Plasmodium yoelii* [14]. Recently, the genomes of seven further primate infectious species have become available, demonstrating the close relationship between Pf and

Antibody response GWAS among Senegalese children [178]
Analysis of global K13 distribution [160]

Fig. 1 Major advances in omics-related fields. This figure highlights landmark studies providing key insights into parasite makeup, development, and pathogenesis (*yellow boxes*) as well as crucial technical advances (*blue boxes*) since the first *Plasmodium* genomes were published in 2002 [2, 5, 12, 13, 27, 29, 31, 39, 40, 42, 43, 48–50, 53, 54, 57, 66, 114, 115, 151, 153–178]. *AID* auxin-inducible degron, *ART* artemisinin, *cKD* conditional knockdown, *CRISPR* clustered regularly interspaced short palindromic repeats, *DD* destabilization domain, *K13* kelch13, *Pb P. berghei*, *Pf P. falciparum*, *TSS* transcription start site, *TF* transcription factor, *ZNF* zinc finger nuclease

chimpanzee infectious species [15]. The typical *Plasmodium* genome consists of 14 linear chromosomes of aggregate size of approximately 22 megabases encoding >5000 protein-coding genes. The core, conserved genome of about 4800 such genes occupies the central chromosomal regions whilst the multigene families (at least some of which are associated with antigenic variation) are largely distributed to the subtelomeric regions. Non-coding RNA (ncRNA) genes [16] and antisense transcription [17, 18] are being catalogued in Pf but this catalogue probably remains incomplete as only blood-stage parasites have been seriously investigated in this regard and ncRNAs remain largely of unknown significance.

One key feature of Pf is its evolution in the face of human-imposed selection pressures in the form of drugs and potentially vaccines. Such pressure has consistently resulted in the emergence of drug-resistant parasites.

Table 1 Key advances from recent omics studies

Research area	Key findings	Reference(s)
Genome sequencing	WGS and refinement of genome sequences of primate and rodent infectious *Plasmodium* species	[13, 154–157, 179]
	Genome sequence of cryptic chimpanzee *Plasmodium* species	[158]
Gene expression regulation	Discovery of AP2-G as master regulator of gametocytogenesis in Pf and Pb	[49, 50]
	AP2-G2 functions as a transcription regulator driving gametocyte development	[51]

There is a huge potential global reservoir of genome variation upon which selection may act. In an initial analysis of 227 parasite samples collected at six different locations in Africa, Asia, and Oceania, MalariaGEN, the Oxford-based genomic epidemiology network, identified more than 86,000 exonic SNPs. This initial SNP catalogue is described in detail by Manske and colleagues [19]. Currently (27 July 2016), the MalariaGEN database states that for the Pf Community Project, it has data on 3488 samples from 43 separate locations in 23 countries and the number of high-quality, filtered exonic SNPs has increased to more than

900,000. All of this variation is diversity, which in turn can be selected for fitter and perhaps more deadly parasites. Modern NGS and WGS have enabled comparative and population genomics approaches that have been used to reveal important features of emerging parasite populations, for example, in response to drugs.

Parasite development and pathogenesis

Within their mammalian host and mosquito vector *Plasmodium* parasites complete a remarkable lifecycle, alternating between asexual and sexual replication (Fig. 2). Throughout the *Plasmodium* lifecycle, regulation of gene expression is orchestrated by a variety of mechanisms, including epigenetic, transcriptional, post-transcriptional, and translational control of gene expression. Owing to the absence of most canonical eukaryotic transcription factors in the *Plasmodium* genome [2], epigenetic control has long been recognized to play an important role in gene expression regulation.

Epigenetics lies at the very heart of gene expression, regulating access of the transcriptional machinery to chromatin [20] via (1) post-translational modifications (PTMs) of histones, (2) nucleosome occupancy, and (3) global chromatin architecture. In the past decade, various histone PTMs have been identified throughout the *Plasmodium* lifecycle (reviewed in [21]) and the existing catalog of modifications in Pf was recently extended to 232 distinct PTMs, 88 unique to *Plasmodium* [22]. The majority of detected PTMs show dynamic changes across the intra-erythrocytic development cycle (IDC), likely mirroring changes within chromatin organization linked to its transcriptional status. Methylation and acetylation of N-terminal histone tails are by far the most studied regulatory PTMs, linked either to a transcriptionally active chromatin structure (that is, euchromatin) or to transcriptionally inert heterochromatin. In Pf, various genes encoding putative epigenetic modulators (that is, proteins catalyzing either the addition or removal of histone PTM marks) have been identified [23], but only a few have been subjected to more detailed investigation [24, 25]. Many of the histone modifiers are essential for *Plasmodium* development, making them a promising target for antimalarial drugs [26]. In Pf, conditional knockdown of HDA2, a histone lysine deacetylase (HDAC) catalyzing the removal of acetyl groups from acetylated histone 3 lysine 9 (H3K9ac), resulted in elevated H3K9ac levels in previously defined heterochromatin regions [27]. H3K9ac is an epigenetic mark associated with transcriptionally active euchromatin [28] and HDA2 depletion resulted in the transcriptional activation of genes located in heterochromatin regions, leading to impaired asexual growth and an increased gametocyte conversion [27]. Interestingly, genes found to be dysregulated by HDA2 knockdown are also known to be associated with HP1, a key epigenetic player binding to tri-methylated H3K9 (H3K9me3), linked to transcriptionally repressed chromatin. Strikingly, conditional knockdown of PfHP1 recapitulated, to a much greater extent, the phenotype observed in HDA2-knockdown mutants [29]. HP1 is believed to act as a recruitment platform for histone lysine methyltransferases (HKMTs), required for maintenance and spreading of H3K9me3 marks [30], which is consistent with the reduction of H3K9me3 observed in HP1 knockdown cells [29]. In addition, bromodomain protein 1 (BDP1) was found to bind to H3K9ac and H3K14ac marks within transcription start sites (TSSs) in Pf, among them predominantly invasion-related genes (Fig. 3a), and BDP1-knockdown parasites consistently failed to invade new erythrocytes. BDP1 also appears to act as a recruitment platform for other effector proteins such as BDP2 and members of the apicomplexan AP2 (ApiAP2) transcription factor family [31].

In addition to histone PTMs, nucleosome organization plays a critical role in gene expression regulation in *Plasmodium*. In general, heterochromatin is substantially enriched in nucleosomes compared with euchromatin [32] and active promoters and intergenic regions in Pf show markedly reduced nucleosome occupancy [33]. In addition, common transcript features such as TSSs, transcription termination sites, and splice donor/acceptor sites show clearly distinguishable nucleosome positioning in Pf [34], but previously described dynamic changes in nucleosome positioning [32] appeared to be mostly restricted to TSSs during the IDC [34]. Uniquely in *Plasmodium* spp., canonical histones in intergenic regions are replaced by histone variant H2A.Z [28], which, in concert with the apicomplexan-specific H2B.Z, establishes a H2A.Z/H2B.Z double-variant nucleosome subtype enriched at AT-rich promoter regions and correlates with open chromatin and active gene transcription [35].

Within the confined space of the nucleus, chromosomes are tightly packed into a three-dimensional structure. This three-dimensional architecture allows interaction between otherwise distant chromatin regions possessing regulatory function and facilitates contacts with other nuclear sub-compartments such as the nucleolus and the nuclear envelope [36]. Until recently, knowledge of the chromosome architecture and chromatin interactions in *Plasmodium* was mostly restricted to single genomic loci based on fluorescence *in situ* hybridization experiments [37]. However, recent advances in deep-sequencing technologies [38] have for the first time enabled the genome-wide profiling of chromosome interactions at kilobase resolution in *Plasmodium* [37, 39].

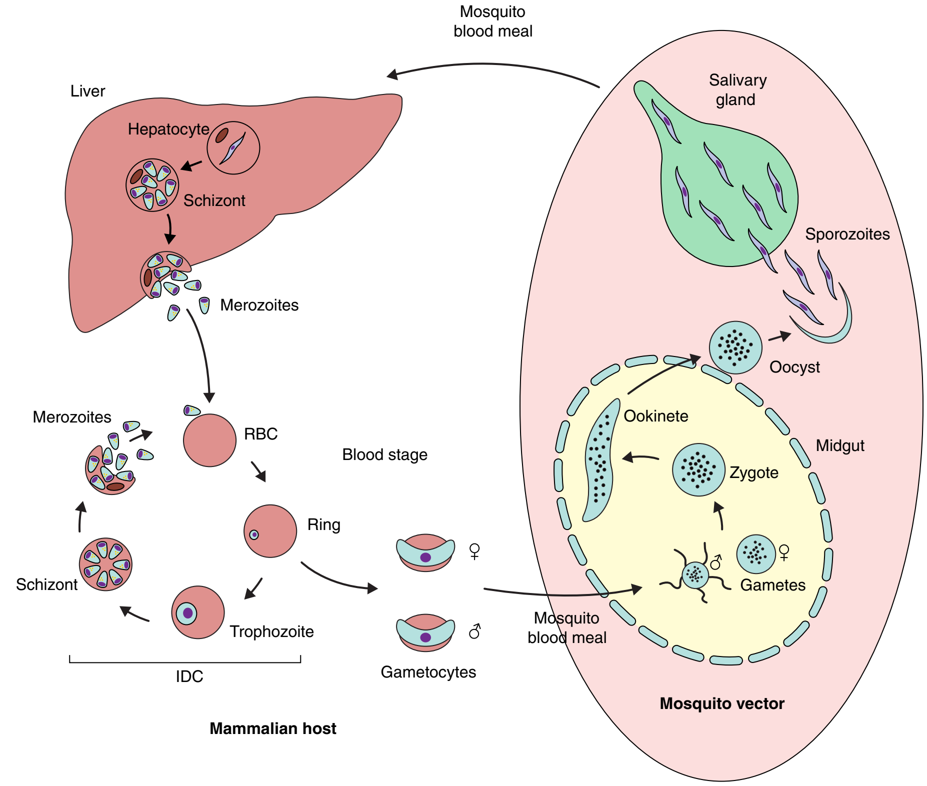

Fig. 2 *Plasmodium* life cycle. After a mosquito bite, malaria parasites are deposited into the host's skin and within minutes are carried via the bloodstream into the liver, where through asexual proliferation within the hepatocytes tens of thousands of merozoites are produced. Following hepatocyte rupture, merozoites are released into the bloodstream where they can invade the host's red blood cells (*RBC*), leading to the initiation of the intra-erythrocytic development cycle (*IDC*). During the IDC (lasting about 48–72 h in human and about 24 h in rodent malaria parasites), *Plasmodium* parasites multiply asexually through the completion of several morphologically distinct stages within the RBCs. After RBC invasion, malaria parasites develop via the ring and trophozoite stage into schizonts, each containing a species-specific number of merozoites (typically 10–30). Upon schizont rupture, merozoites are released into the bloodstream, where they can invade new RBCs and initiate a new IDC. However, a small fraction of ring-stage parasites sporadically differentiate into male or female gametocytes, which are responsible for initiating transmission back to the mosquito. Through another mosquito blood meal gametocytes are taken up into the mosquito midgut where they are activated and form male (eight per gametocyte) and female (one) gametes. Following fertilization, the zygote undergoes meiosis (and therefore true sexual recombination) and develops into a motile, tetraploid ookinete that traverses the midgut and forms an oocyst. Via another round of asexual proliferation inside the oocyst several thousands of new haploid sporozoites are generated that, upon their release, colonize the mosquito salivary glands, poised to initiate a new infection of another mammalian host

In contrast to other eukaryotic organisms, the Pf nucleus appears to lack clearly defined chromosome territories and chromatin interactions are mainly restricted to intra-chromosomal contacts showing a clear distance-related dependency [37, 39]. Inter-chromosomal interactions are mostly absent in Pf and restricted to centromeres, telomeres, ribosomal DNA (rDNA) loci, and internal as well as subtelomeric-localized *var* genes (further discussed in the next section). This observed clustering appears to coincide with transcriptional activity of each cluster. Interestingly, using three-dimensional chromatin modeling, the highly transcribed rDNA genes were proposed to be localized to the nuclear periphery, which was previously mainly associated with transcriptionally silenced heterochromatin [40], indicative of perinuclear transcriptionally active compartments [37].

Transcription itself is initiated through binding of the transcriptional machinery to promoter regions in the nucleus, resulting in the synthesis of pre-mRNA molecules, which, following extensive processing and nuclear export, leads to the accumulation of mature mRNAs in the parasite cytosol [41]. A recent study found evidence for stage-specific transcription initiation from distinct TSSs of otherwise identical transcriptional units, giving rise to developmentally regulated mRNA isoforms [42]. While most canonical eukaryotic transcription factors are absent from the *Plasmodium* genome [2], the ApiAP2 family of DNA-binding proteins comprises by far the largest group of transcription factors in malaria parasites [43]. A collection of ApiAP2 proteins is expressed throughout all stages of the IDC [44], while other ApiAP2 proteins are expressed outside the IDC

Fig. 3 Malaria parasite genomic components involved in pathogenesis. **a** The expression of invasion-related genes is regulated through epigenetic and post-transcriptional mechanisms. Bromodomain protein 2 (*BDP2*) binds to H3K9ac marks within the promoter region of genes associated with red blood cell (RBC) invasion (as well as other gene families not depicted here [31]), enabling their transcription. This is likely achieved through the recruitment of BDP1 and transcription factors (*TFs*) of the ApiAP2 family. Following transcription during the trophozoite stage, mRNAs encoding invasion-related proteins are bound by ALBA1 functioning as translation repressor. After progression to the schizont stage, ALBA1 is released, allowing the timely synthesis of proteins required for merozoite invasion of RBCs. **b** Experimental findings either directly from studies on *ap2-g* or from epigenetically regulated *var* genes are suggestive of an epigenetically controlled mechanism regulating *ap2-g* transcription. In sexually committed parasites, *ap2-g* is characterized by H3K4me2/3 and H3K9ac histone marks and most likely contains histone variants H2A.Z and H2B.Z located in its promoter region. BDPs are believed to bind to H3K9ac, facilitating *ap2-g* transcription. ApiAP2-G drives expression of genes required for sexual development through binding to a 6/8-mer upstream DNA motif. *ap2-g* expression itself is believed to be multiplied through an autoregulatory feedback loop where ApiAP2-G binds to its own promoter that also contains ApiAP2-G motifs. In asexual blood-stage parasites, *ap2-g* is transcriptionally silenced by heterochromatin protein 1 (*HP1*) binding to H3K9me3 histone marks (located in repressive loci in the nuclear periphery). Histone deacetylase 2 (*HDA2*) catalyzes the removal of H3K9ac from active *ap2-g*, facilitating *ap2-g* silencing. **c** Monoallelic expression of one of the approximately 60 members of the erythrocyte membrane protein 1 (EMP1)-encoding *var* genes is regulated through epigenetic silencing of all but one *var* gene copy. The active *var* is marked by euchromatin post-translational modifications H3K4me2/3 and H3K9ac and histone variants H2A.Z/H2B.Z located in its promoter region, as well as H3K36me3 covering the whole *var* gene body but absent from the promoter region. Transcription of noncoding RNAs associated with the active *var* gene is facilitated by upstream as well as intronic promoters. All other silenced *var* genes cluster into perinuclear repressive loci and are characterized by HP1 binding to H3K9me3 marks. *var* gene silencing also involves SET2/vs-dependent placing of H3K36me3 histone marks in promoter regions and is marked by the absence of non-coding RNAs, likely safeguarded through RNaseII exonuclease activity. In addition, other histone code modulators such as HDA2, SET10, and SIR2A/B are likely involved in epigenetic *var* gene regulation. **d** Mutations in *kelch13* (K13) were found to be the major contributors to artemisinin (*ART*) resistance identified in drug-resistant parasites in the laboratory as well as in field isolates. *kelch13* mutations appear to arise in a complex array of background mutations (that is, mutations in genes encoding ferredoxin (*FD*), apicomplast ribosomal protein S10 (*ARPS10*), multidrug resistance protein 2 (*MDR2*), and chloroquine resistance transporter (*CRT*)), not yet detected in African parasites. In addition, elevated phosphatidylinositol-3-kinase (*PI3K*) levels have been observed in ART-resistant parasites and PI3K signaling has been implicated to impact on the unfolded protein response observed in ART-resistant parasites. [45–47]. ApiAP2s appear to be among the main drivers of developmental progress throughout most *Plasmodium* lifecycle stages and their disruption abolishes or greatly reduces parasite development [45, 46]. They bind in a sequence-specific fashion to motifs generally distributed upstream of open reading frames (ORFs) and individual AP2s may have widespread influence; PfAP2-O has been shown to bind upstream of >500 genes (roughly 10 % of the parasite ORFs), potentially influencing a wide range of cellular activities [48].

Through forward genetic screens and comparative genomics, ApiAP2-G was discovered to function as a conserved master regulator of sexual commitment in Pf and Pb. ApiAP2-G binds to a conserved 6/8-mer nucleotide motif enriched upstream of gametocyte-specific genes and *ap2-g* itself, leading to an autoregulatory feedback loop [49, 50] (Fig. 3b). ApiAP2-G2, another ApiAP2 family member, acts downstream of ApiAP2-G during sexual development, functioning as a transcriptional repressor blocking expression of genes required for asexual development and influencing gametocyte sex ratios [50, 51]. During the asexual IDC, *ap2-g* displays characteristics of epigenetically silenced heterochromatin, such as H3K9me3 marks, binding to HP1 and localization to the nuclear periphery (reviewed in [52]) (Fig. 3b). However, the previously mentioned knockdowns of both PfHDA2 and HP1 resulted in increased gametocyte conversion, likely as a direct consequence of the loss of H3K9me3 marks and H3K9 hyperacetylation leading to *ap2-g* transcriptional activation [27, 29]. This opens the possibility of a bet-hedging mechanism for sexual commitment in *Plasmodium*, regulating stochastic, low-level activation of *ap2-g* sensitive to environmental stimuli, as has been shown for several blood-stage-expressed genes [52, 53]. PTMs such as lysine acetylation are not restricted to histones and a recent study has demonstrated that the “acetylome” impacts >1000 proteins and intriguingly is highly enriched in the ApiAP2 transcription factor family [54, 55], although the functional consequences of these PTMs have yet to be established.

Following their synthesis, eukaryotic mRNAs are processed and are finally translated by the ribosomal machinery. Translation has long been a focus of malaria research, not only because it represents a promising target for antimalarial drugs but also for its potential regulatory features [56]. The lack of correlation between transcript and protein level observed throughout the *Plasmodium* lifecycle has fueled researchers’ interest in post-transcriptional and translational control for decades [57]. Many features of post-transcriptional/translational control in malaria parasites are similar to the mechanisms found in other eukaryotes [41]. However, the advent of ribosome profiling [58] has enabled in-depth genome-wide analysis of the *Plasmodium* translatome. Throughout the IDC, transcription and translation are tightly coupled and only 8 % (approximately 300 transcripts) of the transcriptome was found to be translationally regulated [59]. These genes were found to be involved in merozoite egress and invasion, and while transcript level peaked during the late stages of the IDC, maximal translation was observed during the early ring stage. This observation resembles a general feature of gene expression in *Plasmodium*, whereby for a set of genes transcription and translation are uncoupled and mRNA translation occurs during a later developmental time point when compared with maximal transcriptional activity, most notably in female gametocytes [46, 60–64]. This is especially true for genes required for developmental progression and provides the parasite with the capability of rapid and timely protein synthesis without the need for preceding de novo mRNA synthesis. Recently, PfALBA1, a member of the DNA/RNA-binding Alba protein family, was postulated to act as master regulator during the Pf IDC, controlling translation of invasion-related transcripts (Fig. 3a) as well as regulating mRNA homeostasis of approximately 100 transcripts in blood-stage parasites [65]. In contrast to findings by Caro and colleagues [59], an earlier study using polysome profiling found a discrepancy between steady-state mRNA level and polysome-associated mRNAs among 30 % of genes (1280 transcripts) during the Pf IDC, indicative of translationally controlled gene expression [66]. Additionally, the results of this study, as well the findings of others, suggest upstream ORF translation and stop codon read-through in Pf [67–69], but the genome-wide extent of such mechanisms in *Plasmodium* spp. remains controversial [59]. Hence, expansion of these studies to other parasite life stages, such as the gametocyte, where translational control is firmly established, would surely give further insights into the extent of translation regulation in *Plasmodium*.

In addition to canonical protein-coding mRNAs, a vast number of genes encoding different ncRNAs have been identified within the *Plasmodium* genome in recent years, which are believed to exert a variety of regulatory functions (reviewed in [70]). Circular RNAs (circRNAs) are among the newest members of the still expanding catalogue of existing ncRNAs in *Plasmodium* [17]. Host microRNAs (miRNAs) have been shown to regulate parasite translation [71], and circRNAs therefore might act as sponge for host miRNAs, a mechanism described in other organisms [72]. Recent studies have especially increased our knowledge of the role of ncRNAs in *var* gene regulation (discussed in the next section) but, nevertheless, the biological role of the vast majority of these ncRNA species remains unclear.

Immune evasion

In their attempts to occupy a diverse range of host environments, protozoan parasites of the *Plasmodium* genus have evolved a plethora of molecular mechanisms to evade the host adaptive immune response. The host immune response to *Plasmodium* infection is dependent upon both host and parasite genomics and the developmental stage and phenotype of the invading parasite [73–75]. In the best-studied example in *Plasmodium*, virulence of Pf is attributed largely to monoallelic expression of just one of approximately 60 *var* genes that encode variant copies of the surface antigen, Pf erythrocyte membrane protein 1 (PfEMP1). The ability to switch expression from one *var* gene to another enables the invading parasite to alternate between phenotypes of variable cytoadherent and immunogenic properties [76–78]. PfEMP1 proteins are expressed at parasite-induced knobs on the infected erythrocyte surface, which are electron-dense features comprising many parasite proteins anchored to the erythrocyte cytoskeleton. Failure to present PfEMP1 in such knob structures greatly reduces the ability of the infected erythrocyte to bind to its specific host receptor [79].

Pf *var* gene regulation is complex and includes mechanisms of gene regulation such as chromosomal organization and subnuclear compartmentalization [80, 81], endogenous *var* gene clustering and *var* promoter–intron pairing [82, 83], transcriptional gene silencing via exoribonuclease-mediated RNA degradation [84], histone variant exchange at *var* promoters [85, 86], the effect of *trans* antisense long non-coding RNAs (lncRNAs) [87], and the presence or absence of histone modifications and their associated histone-modifying enzymes [27, 29, 40, 87–92] (Fig. 3c). Interest in delineating these mechanisms has continued, and even grown, as more research in the post-genomic area has highlighted the important differential role of the 5′ upstream promoter families into which the *var* genes can be subdivided into five classes (*upsA* to *upsE*), which correlate closely with the severity of malaria infection in the human host [93–98]. Pf *var* gene promoters are also essential components of the gene silencing mechanism and monoallelic expression. The *upsC var* promoter in particular is necessary to maintain chromosome-internal *var* genes in their silenced state and recently has been proposed to do so through the interaction of *cis*-acting MEE2-like sequence motifs and MEE2-interacting factors to reinforce *var* gene transcriptional repression [75, 83].

Monoallelic *var* gene transcription is also associated with the presence of H3K9me3 repressive marks at silent *var* gene loci (Fig. 3c). This histone modification is predicted but not proven to be imposed by the HKMT PfSET3 and is associated with perinuclear repressive centers and the binding of PfHP1, stimulating heterochromatin formation [40, 89, 90, 92]. Conditional disruption of one of these essential proteins, HP1, disrupts singular *var* gene expression and dysregulates antigenic variation [29]. In addition, conditional knockdown of PfHDA2 has been shown to result in a dramatic loss of monoallelic *var* gene expression [27]. This implicated PfHDA2 as an upstream regulator of HP1 binding as it facilitates the establishment of the H3K9me3 mark. The indispensable role of the dynamic histone lysine methylation of *Plasmodium* chromatin by histone lysine demethylases (HKDMs) and HKMTs in controlling the transcription of nearly all *var* genes has also been demonstrated. Knockout of the Pf *hkmt* gene encoding SET2/SETvs (vs, variant-silencing) resulted in reduced presence of the repressive H3K36me3 mark at the TSSs and intronic promoters of all *var* gene subtypes (Fig. 3c). Loss of this SETvs-dependent histone modification resulted in the loss of monoallelic *var* gene expression and expression of the entire *var* repertoire [98]. Furthermore, SETvs can directly interact with the C-terminal domain of RNA polymerase II, with SETvs disruption resulting in a loss of binding to RNA polymerase II and *var* gene switching [99].

Pf *upsA*-type *var* gene expression is also regulated by PfRNaseII, a chromatin-associated exoribonuclease. An inverse relationship exists between transcript levels of PfRNaseII and *upsA*-type *var* genes, with an increase in the latter corresponding to incidences of severe malaria in infected patients [84]. PfRNaseII is proposed to control *upsA*-type *var* gene transcription by marking TSSs and intronic promoter regions, degrading potential full-length transcripts to produce short-lived cryptic RNA molecules that are then further degraded by the exosome immediately upon expression (Fig. 3c). Disruption of the *pfrnaseII* gene resulted in loss of this degradation and the generation of full-length *upsA var* gene transcripts and intron-derived antisense lncRNA. These data illustrate the relationship between PfRNaseII and the control of monoallelic *var* gene transcription and suggest a correlation between lncRNA and *var* gene activation in Pf [84]. The role of lncRNAs in Pf *var* gene activation was again investigated in a study by Amit-Avraham and colleagues [87], which demonstrated dose-dependent transcriptional activation of *var* genes by overexpression of their individual antisense lncRNA transcripts. Disruption of antisense lncRNA expression by peptic nucleic acids resulted in downregulation of active *var* gene transcripts and induced *var* gene switching. The exact mechanism by which antisense lncRNAs act to promote the active transcription of a *var* gene is unknown. It has been postulated that antisense *var* transcripts may recruit chromatin-modifying enzymes that in turn would affect gene accessibility for the Pf transcriptional machinery. Antisense *var* gene lncRNAs would also contain a complementary sequence to *var* gene intronic insulator-like pairing elements that bind specific nuclear-binding proteins, therefore blocking the silencing activity of pairing elements by hybridization [87, 100].

The *Plasmodium* helical interspersed subtelomeric protein (PHIST) family of genes, which is unique to Pf, has also been implicated in the regulation of immune evasion as a result of its ability to bind to the intracellular acidic terminal segment of PfEMP1. Conditional knockdown of the essential PHIST protein PfE1605w reduced the capability of the infected host erythrocyte to adhere to the CD36 endothelial receptor, an important virulence feature of Pf. This study highlighted the importance not only of *var* genes and their controlled expression but also of other genes that are associated with anchoring PfEMP1 to the erythrocyte surface and creating the *Plasmodium* cytoadherence complex [101].

The list of regulatory mechanisms underlying *var* gene monoallelic expression is vast and much more may still be discovered in this area. However, immune evasion in the *Plasmodium* genus is not confined to Pf or *var* gene regulation. Indeed, *var* gene expression is exclusive to Pf, with much still to be gleaned in the areas of immune evasion in human malaria parasites such as *P. vivax*, *P. knowlesi*, *Plasmodium ovale* and *Plasmodium malariae* [13, 102–105]. In addition, PfEMP1 is just one of a number of variant surface antigens (VSAs) known to be expressed at the host erythrocyte surface upon infection with Pf, although it is the best characterized. Pf-infected erythrocytes also express VSAs of the multi-copy gene families of the proteins repetitive interspersed family (RIFIN), subtelomeric variable open reading frame (STEVOR), and Pf Maurer's cleft 2 transmembrane (PfMC-2TM) [106]. The roles of these protein families in antigenic variation and pathology are generally poorly defined but are being elucidated; for example, RIFINs are implicated in the severity of Pf malaria in African children with blood group A. This tendency toward increased malaria pathogenicity is a result of their expression at the surface of infected host erythrocytes, from which they bind uninfected erythrocytes (preferentially, blood group A) to form rosette structures and mediate binding to the host microvasculature [107]. Thus, the combined roles of HP1 and HDA2 in regulating single *var* gene expression and the transcriptional regulator ApiAP2-G suggests that both processes share epigenetic regulatory mechanisms and that *Plasmodium* immune evasion and transmission to new hosts are inextricably linked [27, 29].

Immune evasion is not restricted to blood-stage *Plasmodium*; when the parasite passes through the mosquito it must also combat a sophisticated innate immune system that is very effective in reducing the parasite burden experienced by the vector. A forward genetic screen and WGS was used to identify the key parasite factor, the surface protein PfS47 (found on the surface of the ookinete as it penetrates the mosquito midgut), that appears to interact with and suppress the vector innate immune system [108]. PfS47 is thought to suppress signaling through the c-Jun N-terminal kinase (JNK) pathway that is critical to an effective immune response [109]. WGS demonstrated that PfS47 has a distinct population structure linked to global distribution. PfS47 is rapidly evolving and selected to achieve JNK suppression in diverse mosquito species, which becomes a key step in the adaptation of Pf to transmission in different vectors, thereby contributing to its broad global distribution [110].

Artemisinin resistance

The goals of MalariaGEN characterize a new approach to understanding parasite population biology. Through the generation and, these days more critically, the management and analysis of the colossal datasets that result from WGS of large numbers of samples, a well-organized study can draw meaningful conclusions. This was applied to perhaps the most serious threat to malaria control that has emerged in recent years—resistance to ART. Using these datasets in meta-analyses with clinical data describing the individual WGS-sequenced samples and outcomes of ART treatment allowed a path to be charted that associated SNPs with treatment features (such as delayed clearance) [111] and identified candidate genes [112]: in both studies a region of chromosome 13 was implicated (Fig. 3d). The precise gene encoding the protein KELCH13 was identified by a combination of "old-fashioned" selection of drug-resistant parasites in the laboratory followed by WGS and comparative genomics of the sensitive parental parasites and the progeny, as well as WGS of ART-resistant field isolates [113, 114]. The role of the *kelch13* mutations in ART resistance was proven by direct genome engineering of *kelch13* to generate resistant parasites [115, 116]. *kelch13* SNPs have been used to map the alarmingly rapid spread of resistance throughout Southeast Asia [116] and it is clear that there is already significant but distinct *kelch13* heterogeneity in African Pf strains, although there is no evidence of ART resistance [117–121]. However, in-depth analysis of Southeast Asian ART-resistant parasite genomes [122] revealed that a complex array of background mutations (Fig. 3d) in a variety of genes (encoding ferredoxin (FD), apicoplast ribosomal protein S10 (ARPS10), multidrug resistance protein 2 (MDR2), and Pf chloroquine resistance transporter (CRT)) that are not yet described in African parasites would explain why ART resistance is not (yet) a threat to the use of ART in that continent [121].

A further puzzle was the large number of independent SNPs that seemed capable of mediating ART resistance—typically drug resistance is generated by one or a small number of SNPs focused on either altering the target binding site for the drug or preventing drug access to a binding site buried in the target structure. KELCH proteins are propeller proteins with an iterated structural motif that serves as a platform for the assembly of multiprotein complexes. In addition, KELCH13 has a BTB/POZ domain that might be involved in homodimerization, E3 ubiquitin ligase binding, and transcriptional repression (reviewed in [123]). It has been suggested that ART-resistance-associated *kelch13* SNPs might cause a degree of reduced binding of Pf phosphatidylinositol-3-kinase (PI3K), which in turn results in its reduced ubiquitination and consequent degradation of PI3K (Fig. 3d). Elevated levels of PI3K generate increased amounts of its lipid product phosphatidylinositol-3-phosphate (PI3P), which then changes the physiological state of the parasite cell through signaling in as yet unknown pathways [124] but through a mechanism predicated on the proposed abundance of PI3P in the lumen of the endoplasmic reticulum and its proposed role in protein export beyond the parasite vacuole within the host cell [125]. However, aspects of this view have been challenged [126] and further studies are clearly required to resolve the possible role of PI3K signaling in ART resistance. It will be of interest to see if PI3K signaling impacts upon the unfolded protein response implicated in ART resistance using population transcriptomics [127]. The WGS data and two proteomics studies [128, 129] that demonstrate the wide variety of proteins from different cellular compartments of the target parasite that interact with activated ART together suggest that ART resistance is a pleiotropic phenomenon [123]. Therefore, other interrogations, such as metabolomics (see next section), might also be needed to gain functional insights into ART's mode of action.

Translational implications for malaria control

Antimalarials

WGS has been instrumental in identifying the cellular target of novel Pf antimalarials as part of the drug discovery pipeline and in following the in vitro selection of resistant parasite lines and validation of observed genomic changes by reverse genetics as described for ART above. This approach has proved highly successful for spiralindolines [130], resulting in the identification of the target of NITD609 (also known as KAE609 or cipargamin) as the P-type ATPase PfATPase4. Furthermore, the translation elongation factor eEF2 has been identified as the target of the 2,6-disubstituted quinoline-4-carboxamide scaffold derivative DDD107498 [131]. WGS is not the only post-genome approach that is useful for determining modes of drug action; metabolomics has a similar potential for analyzing the metabolic changes produced in response to drug exposure and has been utilized in antibiotic [132] and anti-protozoan drug [133] investigations. A metabolomics-based approach also has the advantages that parasite lines resistant to the drug need not be generated and that the activity of pleiotropically acting drugs (such as ART) are directly observed rather than imputed from genomes of resistant parasites.

Vaccines

Post-genomic approaches have also identified promising new Pf vaccine candidates. For example, Pf reticulocyte-binding protein homologue 5 (RH5) binds to the human red cell surface receptor protein basigin, an interaction that is essential for erythrocyte invasion by Pf [134]. Recent WGS studies have shown that both the host and parasite proteins are highly conserved, that antibodies to RH5 block merozoite invasion of erythrocytes [135, 136], and that basigin itself is druggable by recombinant antibodies [137]. Although RH5–basigin interaction offers great promise, the challenges for vaccine development remain considerable and many promising candidates have fallen or will fall by the wayside due to an inability to formulate them to deliver effective vaccination, massive candidate gene sequence variability, and functional non-essentiality of the candidate. WGS will help identify non- or minimally variant candidates and should prove useful in monitoring the effect of vaccination and the analysis of "breakthrough" parasites (those developing in vaccinated individuals), as described in the next section. Effective subunit vaccines will be an invaluable additional approach to vaccination, supplementing other approaches such as the use of the promising but technologically challenging attenuated whole parasite, for example, sporozoite vaccine [138].

Surveillance

The identification of genome signatures of resistance through WGS in the laboratory and increasingly through large-scale genomic epidemiology provides a powerful tool to monitor the emergence of resistance in *Plasmodium* populations under selective pressure due to administration of both drugs and vaccines. In the case of drugs whose targets have been identified in the laboratory, specific, simple PCR-based assays can be devised. WGS of field parasites under drug pressure is still desirable, however, as alternative resistance mechanisms might emerge that would be missed by targeted assays and, with sufficient depth of sampling, new signatures of resistance would be identifiable from the sequence data. Similar surveillance of parasites that emerge post-vaccination might also be informative. An important analysis of the clinical trial of the RTS,S/AS01 malaria vaccine compared the strain-specific sequence of the gene encoding the circumsporozoite (CS) protein that comprised the vaccine with the CS gene sequences of strains in the infections actually encountered by immunized individuals (between 5 and 17 months of age) [139]. This study demonstrated that homologous protection was greater than protection against heterologous strains and that a cause of failure to protect was simply that the CS protein carried by the infecting parasites did not match that of the vaccine and so perhaps a protective effect was less likely [139]. Therefore, WGS has the power to guide vaccine design based upon the outcomes of trials.

Gene editing

A new era of genetic engineering has dawned with the discovery and development of the bacterial guide RNA template-targeted clustered regularly interspaced short palindromic repeats (CRISPR)-Cas9 recombinases as tools for the accurate editing of genomes. The technology has been successfully adapted to many species, including *Plasmodium* [140], *Anopheles* [141, 142], and humans (discussed in [143]). Currently, applications of CRISPR-Cas9 to *Plasmodium* manipulation are restricted to reverse genetic investigations of gene function. However, with the concepts of whole (pre-erythrocytic) parasite vaccines [144, 145], CRISPR-Cas9 offers an obvious route towards the generation of an immunogenic, non-pathogenic parasite that might be suitably safe to administer to humans as a vaccination strategy. Clearly, the engineering of human genomes at any stage of gestation is fraught with ethical considerations [146] and it is inconceivable that this will be applied to the improvement of human resistance to malaria in the foreseeable future. Conversely, although subject to similar ethical and ecological debate, significant conceptual advances towards the generation of CRISPR-Cas9-engineered *Anopheles* mosquitoes have been quickly achieved. Through harnessing the concept of gene drive, two independent teams have reported the generation of either engineered *Anopheles stephensi* (a major Indian vector of malaria) that is resistant to malaria [141] or sterile female Ag [142]. Again, owing to ecological considerations, it is unlikely that such engineered mosquitoes, although clearly feasible, will be released into the wild any time soon [147].

Conclusions and future directions

Despite the progress summarized here, the fundamental requirements of malaria research in any era remain the same; namely, new drugs to replace those that become ineffective, vaccines that work, and the means to administer them effectively. Genomics, post-genomic technologies, and associated computing developments have revolutionized investigations into the biology of the malaria parasite and the search for therapeutics or intervention measures. Significant progress has been made on many fronts, including candidate drug and vaccine discovery, parasite drug resistance mechanisms, host–parasite–vector interactions and parasite biology, and mechanisms of human resistance to malaria. Also, new concepts of combatting malaria via engineered mosquito populations have been introduced through the advent of novel genome-editing approaches such as CRISPR-Cas9.

We can anticipate that WGS will continue to improve in terms of both cost and quality, making sequencing of every desirable Pf isolate feasible. This would enable more detailed studies of population structure and dynamics, allowing the tracking of gene flow and genotype success that might even resolve at the village level and, further, potentially almost in real time. However, this will only happen if data storage, access, and computing technologies keep pace. Where Pf WGS studies have gone *P. vivax* research will follow and recent studies have revealed signatures of drug selection superimposed upon a far more complex (global, regional, and even within a single infection) population structure than Pf [148, 149]. Single-cell RNA sequencing will significantly improve our understanding of antigenic variation and variant and sex-specific gene expression.

More immediately, an important need is for surveillance, particularly in Africa, to look for *kelch13* mutations and genotypes associated with ART resistance and a pan-African network is in place to monitor for this and collect samples [150]. Genomics will continue to be used in novel ways as well, for example, in studies of the outcomes of human interventions such as drug treatment and vaccination.

New fields of endeavor are also emerging that will certainly prove fruitful in the years to come. Lipidomics is a nascent discipline that will no doubt reveal insights into membrane composition and organization [151] and might also open avenues to therapy. PTMs such as palmitoylation give proteins the means to conditionally interact with membranes and *Plasmodium* makes extensive use of protein palmitoylation that should influence a range of important parasite biological activities, such as cytoadherence and drug resistance [152].

Although the power of genomics approaches is quite clear, direct biological investigations are frequently required to confirm or refute the findings that genomics might imply. The numerous examples given here indicate that although genomic analyses often generate associations and degrees of confidence about their conclusions, unequivocal confirmation is provided by genetic engineering (of parasites and their vectors at least). Genetic screens are powerful, often unbiased approaches to discover gene function. The recent development of the PlasmoGEM resource coupled with high-efficiency transfection and barcoded vectors permits genome-scale reverse genetics screens to be deployed that will undoubtedly reveal information about parasite-specific genes and *Plasmodium* biology [153]. Finally, many of the genes encoded by parasite, host, and vector genomes have unknown functions, the details of which are slowly emerging as technologies and assays improve. The staggering complexity of organismal biology and the interactions between parasite, host, and vector will continue to amaze but equally will offer hope for new and improved therapies.

Abstract

The Genomics Workgroup of the National Advisory Mental Health Council (NAMHC) recently issued a set of recommendations for advancing the NIMH psychiatric genetics research program and prioritizing subsequent follow-up studies. The report emphasized the primacy of rigorous statistical support from properly designed, well-powered studies for pursuing genetic variants robustly associated with disease. Here we discuss the major points NIMH program staff consider when assessing research applications based on common and rare variants, as well as genetic syndromes, associated with psychiatric disorders. These are broad guiding principles for investigators to consider prior to submission of their applications. NIMH staff weigh these points in the context of reviewer comments, the existing literature, and current investments in related projects. Following the recommendations of the NAMHC, statistical strength and robustness of the underlying genetic discovery weighs heavily in our funding considerations as does the suitability of the proposed experimental approach. We specifically address our evaluation of applications motivated in whole, or in part, by an association between human DNA sequence variation and a disease or trait relevant to the mission of the NIMH.

Introduction

Mapping the relationship between human genetic and phenotypic variation is a challenging task for human biology. When such variation is so extreme as to disrupt normal functioning, it becomes a major challenge for medicine as well. In an effort to address this, and as part of its mission to advance mental health research, the United States' National Institute of Mental Health (NIMH) supports a broad research program in human genetics. The overarching goal is to uncover psychiatric disease mechanisms grounded in human biology.

It is clear for psychiatric disorders, and other complex disorders, that there is no simple unitary mapping between a gene and disease. For any given individual, genetic risk is a unique combination of many variants, from common to rare, that are often shared across psychiatric diagnoses. Even in the case of rare disorders and highly penetrant mutations, the cumulative genetic inheritance of the individual has a strong influence on the type and severity of the clinical presentation [1, 2]. Thus, when basic researchers ask, as they often do, "*Which gene should I study for [insert psychiatric disorder]*," the answer is not as straightforward as the question implies because it belies the underlying complexity. Indeed, the study of single genes, in isolation, may be inadequate for understanding the pathogenesis of common psychiatric disorders and should be supplanted with approaches addressing the complex interplay of genomic and other risk factors in shaping phenotypic outcome [3].

In an effort to enhance its psychiatric genetics research program and prioritize follow-up studies, the NIMH convened the Genomics Workgroup of the National Advisory

Mental Health Council (NAMHC) comprised of geneticists and neuroscientists. Their recommendations emphasize the primacy of rigorous statistical support from properly designed, well-powered studies for pursuing genetic variants reliably associated with disease [4]. In light of these recommendations, here we provide broad guiding principles for investigators to consider when conducting studies motivated in whole, or in part, by an association between human DNA sequence variation and a psychiatric disorder or related trait. When evaluating proposed studies, we weigh these points in the context of reviewer comments, the existing literature, and current investments in related projects. Following the NAMHC report, statistical strength, and robustness of the underlying genetic discovery weighs heavily in our funding considerations as does the suitability of the proposed experimental approach. Importantly, discovery in human genetics is proceeding rapidly and genetic risk factors identified through various rigorous study designs and analytic methods across multiple cohorts and studies are more likely to stand the test of time and warrant deeper investment.

From genetic architecture

A critical lesson from the past decade of human genetics research is that regardless of whether variants are common or rare, occur in coding or noncoding regions, or alter single base pairs or large segments of the genome, strict statistical methodology is required to identify robust associations with a disease or trait. Deciding which variants to pursue for biological follow-up thus requires understanding what the initial genetic discovery does and does not tell us about the relationship to disease.

A now-common approach for genetic discovery is genome-wide association (GWA) studies. These identify statistical relationships between common single nucleotide variants across the entire genome and a phenotype of interest. Critically, they implicate regions of the genome (loci) and do not necessarily pinpoint the causal variant(s), gene(s), or mechanism(s) underlying the association. When assessing GWA findings from the literature, caution is warranted because published studies may simply list genes within risk regions, and this may give the false impression that these are the relevant disease genes. For complex traits, hundreds of regions and potentially thousands of genes may be involved that require tens to hundreds of thousands of subjects to identify [5–9]. Approaches that take into account the cumulative effects of these numerous and subtle changes in gene function may thus be more informative with regard to disease mechanisms than those focusing on individual, associated variants or genes [10].

In another approach, rare variant association studies identify genes across the genome that harbor more mutations in a group of subjects (e.g., ASD cases) compared to a well-matched group (e.g., ASD siblings) or expected by background mutation rates [11–13]. Due to limited power, sequencing studies of rare protein coding ("exome") variants often implicate genes and specific mutation categories (e.g., loss-of-function or missense mutations), but seldom individual variants. Given that each of us carry hundreds of protein altering mutations, some of which are damaging, rigorous statistical methods are required to guard against biologically interesting yet irrelevant associations [14]. Rare variant discovery methods differ in their assumptions, power, error rates, and how they leverage genetic and nongenetic information to identify genome-wide statistical associations [15–18]. With any approach, a highly rigorous statistical framework is essential [19]. In some cases, more liberal statistical thresholds may be appropriate to identify larger sets of genes to be interrogated collectively, either bioinformatically or experimentally, where the biological signal prevails over the noise. With limited resources, however, a conservative approach relies on the strictest statistical criteria to select genes of high confidence for deep, targeted experimental follow-up (see Supplemental information).

In some cases, symptoms of rare diseases and syndromes may overlap with those of more common and etiologically complex disorders. For example, individuals with Fragile X or velocardiofacial syndromes often have features of autism or schizophrenia, respectively. Although these syndromes have well-defined genetic causes, the manifestation of different symptoms is likely influenced by other genetic factors. Thus, mutations in *FRM1* and copy number variants (CNVs) of 22q11 that cause these syndromes should not be considered synonymous with autism or schizophrenia. In fact, the more common neurological feature for both these syndromes is intellectual disability [20, 21]. Even in the case of fairly penetrant variants such as CNVs, unbiased genetic associations are required to establish a definitive link between these variants and a psychiatric diagnosis [22]. This holds true for individual genes within large, multigenic CNVs. Currently, there is no robust statistical genetic evidence that these CNVs can be resolved to individual risk genes [17] nor are there consensus functional experiments for determining which gene or genes within or near an associated CNV is driving disease risk.

Overall, there are many factors to consider when assessing the strength of evidence for a genetic association and it may be difficult without familiarity of statistical or quantitative genetics (see Supplemental information for an FAQ). We recognize that there are still only a handful of causal variants and genes with a high level of statistical confidence across psychiatric disorders, but we expect this number to grow with increases in sample size, better functional annotation and improved methods for causal inference [23].

Box 1. Points to consider when experimentally following up human genetic findings

A. Assessing the strength of the evidence for genetic association with a disease or trait

- Is the genetic association statistically robust using an unbiased, genome-wide approach (e.g., genome-wide significant)? Has it been replicated? What is the effect size?
- For large, multigenic CNVs, have any individual gene(s) been statistically associated genome wide?
- Has the genome-wide significant signal been statistically narrowed down (i.e., fine mapped) to a causal variant, gene, and/or isoform(s)?
- What other diseases or traits has the variant or gene been associated with? How does that inform the design and interpretation of the proposed experimental study?

B. Experimental study design based on the variant(s) or gene(s) of interest

- Has the functional variant(s) been identified? Does it cause a gain or loss of function? Does it increase or decrease gene expression? Splicing? Transcription factor binding?
- In what human tissues and cell types is that variant active? During which developmental period(s)?
- How conserved is the implicated genomic element or corresponding gene(s) across species? How about the regulatory regions? Or the gene's coexpression and/or protein interaction network across cells, tissues, and developmental periods?
- Do genome-wide enrichment analyses for the trait or disease identify those same cells, tissues, and developmental periods?
- Is the function of the gene, isoform, or effect of the variant robust across multiple cell lines and animal strains?
- Is the proposed experimental system appropriate given the conservation of the genomic element, gene, or isoform and its expression across cell, tissues, developmental periods, and/or species?
- If studying risk variants or genes individually or collectively, is there an appropriate set of well-matched control variants or genes?

C. Maximizing utility and impact of the approach

- Is the proposed experimental approach best suited to address the mechanism of disease risk conferred by a particular genetic variant or to investigate the basic biology and function of the variant and corresponding gene/isoform(s)?
- Given the question of interest, what is the trade-off between a deep dive into the biology and function of a particular gene or variant versus a comprehensive assessment of all genome-wide significant, disease or trait-associated genes or variants?
- Have the experimental effects of genes or variants been considered in the context of all clinical and nonclinical traits associated with those same variants as well as whether nonassociated genes or variants have similar effects?

We provide some suggestions (Box 1a) for prioritizing where to focus experimental efforts to gain relevant biological traction.

To biology

Once a reliable association is identified, the crucial and more difficult step is transforming that genetic discovery into biological insight. Although true genetic associations must, by necessity, signal a causal effect, that effect may be indirect and far removed mechanistically from the trait of interest [24]. This has important implications for the selection, design, and interpretation of experimental paradigms. Psychiatric disorders lack specific markers and genetic variants often influence many traits (i.e., pleiotropy) [25]. This reality limits the ability to draw causal inferences about disease mechanisms. It is thus critical to clearly define the research question and carefully select the most appropriate experimental system to address that question (Box 1b). To illustrate these points, we provide and evaluate five examples of hypothetical studies related to mental health aiming to biologically follow-up genetic findings.

(1) Embracing pleiotropy and polygenicity

> *Analyses of well-powered GWA and exome studies show that implicated genes as a whole are preferentially expressed in region X of the human brain relative to other regions. Region X consists of a mixed population of cells that project to different downstream brain regions. Our preliminary data indicate that well-powered GWA and sequencing studies from related diseases also show an enrichment, albeit weaker one, in region X. Our data further indicate an enrichment of orthologous genes in brain region X of species Y. Here we use our method of isolating cells*

> *based on their projection targets in species Y to better resolve the genetic enrichment observed across these diseases into projection-specific cell types. We will further develop transcriptional signatures of these cells and validate our findings in human brain. This study will increase our understanding of how genetic risk across related diseases map onto specific cells and circuits in the brain.*

This proposed study does not focus on any one gene or gene variant, but rather follows up on well-powered analyses that take into account many potential genes associated with disease. Furthermore, given the known overlap in the causes and symptoms of psychiatric disorders, it does not focus on any one disease. It takes a finding based on human genetics and human tissue, identifies a similar biological signal in another species, then leverages that experimental system to further refine that signal and validate it back in humans. Using genetic information in this manner may reveal common biological mechanisms that would otherwise be missed by single gene and single disease studies.

(2) Getting back to basics

> *Gene X has been fine-mapped as a likely causal gene within a genome-wide significant disease risk locus and replicated across multiple cohorts. (Alternatively, gene X has a genome-wide significant increased* mutation *burden in cases versus controls across multiple cohorts). Here we propose to further understand the function of gene X in the brain. Our preliminary data show that in both an experimental organism and humans gene X is most highly expressed in a specific cell type known to be important for a particular process. We will transcriptionally profile this cell type across development in the organism to identify the time course of gene X expression and determine if it coincides with the maturation of the relevant cellular process. We will also transcriptionally profile wildtype and conditional, cell-type selective gene X knockout cells, assess the impact on the cellular process and identify potential molecular mechanisms via rescue of differentially expressed targets. This study will advance our understanding of gene X biology.*

Although this proposed study is based on a statistically robust genetic finding, it is intended as a basic science study into the biology of gene X. The strength of the study depends on how much and how well it will advance our understanding of gene X and/or fundamental principles of biology. These findings may or may not be relevant for understanding how human genetic variation in gene X contributes to variation in disease risk, but it will contribute basic knowledge whose ultimate impact will be determined in the future.

(3) Updating poor priors

> *A recent genome-wide association study identified 12p34 as a genome-wide significant disease risk locus. Interestingly, one of the three genes within the risk locus is gene X that is part of a pathway long hypothesized to be involved in disease pathogenesis. How gene X is involved in this pathway is still not fully understood. Our preliminary data show that manipulating expression of gene X produces changes in the pathway similar to those observed in patients. Here we will use a series of loss- and gain-of-function experiments to characterize how the function of gene X influences the function of the pathway. This study will advance our understanding of gene X and how it contributes to disease.*

This proposed study is based on the location of gene X within a genome-wide significant risk region. There is, however, no evidence that the association with disease is operating via that gene as opposed to the other two genes within the region or possibly other more distant genes. Such evidence would require a statistical and/or functional fine-mapping procedure [26, 27]. The information that gene X is part of a disease-relevant pathway may appear to provide a strong prior for focusing on that particular gene. Yet, in the absence of a formal unbiased assessment of how many pathways have been associated with disease, how many genes are within each of those pathways, how these genes are distributed across the genome, or how many risk regions and genes overlap with those regions, it is not possible to determine whether this is a chance occurrence or not. There may be other lines of evidence that indicate gene X and its pathway are important to study in terms of fundamental biology, but in this example the evidence of disease relevance is circumstantial and may in fact detract from the potential basic science value of the study.

(4) Studying rare variants

> *Gene X has a genome-wide significant increased burden of heterozygous loss-of-function mutations in cases versus controls across multiple cohorts using various analytic methods. In order to understand disease pathogenesis and pathophysiology, here we propose to characterize the effects of gene X knockout at the molecular, cellular, and behavioral levels in an experimentally tractable organism. Our preliminary data show disease-like deficits in behavior that are*

rescued by expressing gene X in adult animals. This study will identify the molecular and cellular mechanisms by which gene X causes disease and identify potential therapeutic targets.

Although this proposed study is based on a statistically robust genetic finding, there are limitations to the experimental approach. The application proposes characterization of an animal knockout (null allele) that may or may not mimic heterozygous loss-of-function mutations observed in patients. The goal is to explore disease pathogenesis and pathophysiology and not the basic biology of the gene, but the proposal assumes that because mutants exhibit "disease-like" behavioral deficits, changes at the molecular, or cellular level will be de facto relevant for understanding human disease mechanisms. Such changes must be interpreted in a wider biological and clinical context. For example, how many null mutations in other genes not associated with the disease cause similar changes in the organism? This problem may be mitigated by collectively studying multiple disease-associated genes to look for common patterns of effects. Yet, that design would require an appropriate set of well-matched control genes assessed for similar changes. Critically, "disease-like" behavior in an animal does not establish a causal link among a gene, molecular/cellular effect, and disease nor does the absence of such behavior refute it.

It is important to keep in mind that loss-of-function mutations in particular genes are often associated with multiple neurological and psychiatric phenotypes in people, are not fully penetrant and are modified by polygenic effects [2, 28]. This lack of specificity at both the genetic and phenotypic levels should guide and constrain the interpretation of phenotypes observed in mutant organisms. In general, broad characterization of mutant animals are less informative than those that first take into account wider biological and clinical factors to formulate well-defined research questions (Box 1).

(5) Studying common variants

Gene X has been fine-mapped as a likely causal gene within a genome-wide significant disease risk locus and replicated across multiple cohorts. In order to understand disease pathogenesis and pathophysiology, here we propose to characterize the effects of gene X knockout at the molecular, cellular, and behavioral levels in an experimentally tractable organism. Our preliminary data show disease-like deficits in behavior that are rescued by expressing gene X in adult animals. This study will identify the molecular and cellular mechanisms by which the gene causes disease and identify potential therapeutic targets.

This proposed study is similar to the previous example except that it is based on a common variant association mapped to a gene. In addition to the limitations noted above, the approach has the added issue of attempting to recapitulate, with a null allele, what are often subtle, cell-type specific regulatory effects of common noncoding variants. These risk variants in humans are typically of low effect and operate in the context of hundreds of other such variants. The biological effect of a null allele in an experimental system is thus not necessarily related to a single risk variant in the context of this polygenic effect in humans. It is for this reason and those mentioned above that studies attempting to create a genetic 'model of disease' are potentially more problematic than those focused on either the basic biology of likely causal variants, or their associated genes, within a risk locus or a more integrative approach that accounts for a multitude of risk variants [29].

Summary

The recent and rapid progress in psychiatric genetics has simultaneously created a set of opportunities and challenges (Box 1c). Previously, when genetic clues were scarce, investments in experimental studies tolerated potential false alarms to avoid possible misses for much needed hits. Now, however, with a steady stream of reliable genetic findings, false positives have the danger of diverting precious resources. The availability of large-scale, multidimensional genetic, and genomic datasets combined with incentivized motivated reasoning, confirmation bias, and apophenia [30] poses the danger of generating appealing but unsupported biological narratives. An emphasis on the strength of statistical support for genetic discoveries serves as an important check and a guide for resource investment. This does not imply that genetics are not informed by prior knowledge and biological data, but such information needs to be formally and rigorously incorporated into the whole body of evidence [14, 31, 32], not applied in an ad hoc manner—it is important to systematically integrate statistical and biological evidence to reduce the risk of introducing bias. We hope that such an approach, coupled with appropriate experimental systems, will at most reveal disease-relevant mechanisms and at least advance our understanding of fundamental biology.

Acknowledgements We wish to express our gratitude to the members of the NIMH Genomics Team and Drs Josh Gordon and Naomi Wray for their helpful comments and suggestions. We thank Lora Bingaman for her tireless support of the NIMH Genomics Team and its deliberations and for her editorial assistance with this manuscript.
